Fluorodeoxyglucose (FDG) positron emission tomography/computed tomography (PET/CT) has been shown to have a role in the diagnosis of the postoperative recurrence of pancreatic adenocarcinoma. In one study, PET/CT correctly detected local recurrence in all cases of recurrence in patients who had surgery, whereas MDCT alone detected the recurrence in 64% of cases, suggesting that PET/CT is superior in these patients.^{166,167}

Magnetic Resonance Imaging

Several reports have compared the efficacy of MRI with CT, with variable results. The earliest studies, which were generally performed with low-field-strength magnets and without gadolinium, showed either a superiority of CT or equivalent results.¹⁶⁸ Later studies using dynamic contrast enhancement with gadolinium suggested a superiority of MRI.^{169,170} A large prospective study comparing state-of-the-art helical CT and MRI examinations needs to be performed.

MRI, magnetic resonance angiography, and cholangiopancreatography are comparable to CT in evaluating a suspected pancreatic mass and may be particularly valuable when CT findings are indeterminate. Evaluation of acute and chronic pancreatitis as well as of their complications can be successfully accomplished with MRI. In addition, MRI is a viable alternative to CT when there is a history of allergy to iodinated contrast material or when examination of the biliary tree is requested.^{171,172}

Multiple recent advances in abdominal MRI, including the development of high-gradient systems and the advent of parallel imaging, allow optimal imaging of the pancreas. The most important sequences for the evaluation of the pancreatic parenchyma are precontrast T1-weighted spoiled gradient-echo with fat suppression and dynamic imaging after intravenous administration of gadolinium. On precontrast T1 fat-suppressed sequences, the normal pancreas has high signal intensity relative to the liver because of the presence of acinar proteins.^{171,172} More recently, advances in MR gradient technology and fast imaging

techniques have permitted diffusion-weighted imaging and measurement of the apparent diffusion coefficient, which has become another important tool in MRI of the pancreas. Diffusion-weighted imaging is a relatively quick sequence to obtain and provides great tissue contrast. In addition, diffusion-weighted imaging requires no contrast material administration. Studies have shown that diffusion-weighted imaging and apparent diffusion coefficients not only are helpful in detecting pancreatic tumors but also can assist in detecting tumor spread and response to therapy.

T2-weighted sequences are especially useful for the evaluation of the biliary tract and pancreatic duct. These sequences can accurately depict pseudocysts, fluid collections, gallstones, and choledocholithiasis. MRCP, which is based on heavily T2-weighted sequences, has been increasingly used as the first-line modality for diagnostic purposes, with ERCP ensuing when necessary, thereby avoiding potential complications related to endoscopic technique, particularly when it is used for screening and in asymptomatic individuals. The ability to perform dynamic imaging, functional evaluation of the pancreas, and overall excellent diagnostic yield, even in rare pathologic processes, render MRCP an indispensable diagnostic tool in modern gastroenterology.^{173,174}

MRCP is excellent for the evaluation of changes in the anatomy of patients after pancreaticobiliary surgery, particularly with biliodigestive anastomoses and nondilated bile ducts.¹⁷⁴ It is reliable, fast, safe, and noninvasive and can be used to screen symptomatic patients for treatment, to help guide further therapeutic procedures, or for follow-up.¹⁷³

Other techniques that can aid in the preoperative assessment of resectability are endoscopic ultrasound and laparoscopy.¹⁷⁵ Laparoscopy and limited staging surgery and laparoscopy with laparoscopic ultrasound are routinely used at some centers before definitive laparotomy in an attempt to decrease unnecessary surgeries.¹²² In a recently published meta-analysis, it was reported that on average, performing diagnostic laparoscopy with biopsy and histopathologic confirmation of suspicious lesions before laparotomy would avoid 23 unnecessary laparotomies per 100 patients in whom pancreatic surgery with curative intent is planned on the basis of findings on CT.

Intraoperative Ultrasound

Intraoperative ultrasound is helpful in the detection of small and elusive pancreatic neuroendocrine tumors. In patients with carcinoma of the pancreas, intraoperative sonography is useful in locating a nonpalpable neoplasm, staging the extent of disease, defining its relationship to adjacent structures, and providing guidance for a variety of procedures.¹⁷⁵⁻¹⁷⁸ The exact stage of disease and potential resectability can be determined immediately after laparotomy but before tissue dissection. Tumor invasion, particularly in the portal venous system but also hepatic metastatic disease and regional adenopathy, is easily assessed with intraoperative sonography.¹⁷⁵

Intraoperative ultrasound is also useful in patients with pancreatitis for localizing and characterizing pseudocysts and other fluid collections. These collections are often difficult to localize by direct visualization and palpation during surgery owing to the presence of dense surrounding inflammatory tissue and necrosis.^{175,178-181} In patients with chronic pancreatitis, the dilated pancreatic duct can be localized sonographically for intraoperative pancreatography, surgical decompression, or other surgical procedures^{175,181} (Fig. 99-6).

Figure 99-6 Intraoperative ultrasound of the pancreas for localization of the pancreatic duct before decompressive surgery. The pancreas is well visualized with intraoperative sonography (long arrows). Note the dilated pancreatic duct, measuring 6 mm in diameter. The needle tip is seen entering the pancreatic duct (short arrow).

TYPES OF PANCREATIC OPERATIONS AND POSTOPERATIVE RADIOLOGIC FINDINGS

Sphincterotomy

Surgical sphincterotomy is one therapeutic approach to patients with sphincter of Oddi spasm and pancreas divisum. After surgery, CT, ultrasound, and plain films may show intrabiliary and, more rarely, pancreatic ductal gas. On upper gastrointestinal studies, reflux of barium into the bile duct is common. Because the barium quickly empties into the duodenum, the reflux is usually not clinically significant.^{52,116,182,186}

Puestow Procedure

A Puestow procedure may be considered in patients with severe abdominal pain associated with chronic pancreatitis and pancreatic duct dilation (>6 mm) associated with obstruction and strictures.^{187,188} In these patients, an extended longitudinal incision is made throughout the length of the duct until all the strictures are opened (Fig. 99-7). The duct is then anastomosed to a Roux-en-Y loop of jejunum, which provides drainage at the obstructed regions. The procedure allows good postoperative pain relief in 60% to 80% of patients and maintains pancreatic function by providing wide ductal drainage without pancreatic resection.¹⁸⁹⁻¹⁹² These patients usually do not show any abnormalities of the stomach, duodenum, or upper jejunum on gastrointestinal studies unless barium or air refluxes into the afferent loop. On rare occasions when barium does reflux, it is of no significance unless there is prolonged retention of contrast material by the afferent loop or fistula formation.¹⁸²⁻¹⁸⁶ On CT examination, when the anastomosis contains fluid or air, it may mimic a pancreatic or peripancreatic abscess. In addition, soft tissue seen normally anterior

to the pancreatic body or tail from the jejunal anastomosis to the pancreas can mimic a tumor or an internal hernia if the radiologist is not aware that the patient has undergone a Puestow procedure.^{188,189}

Frey Procedure

This procedure has been gaining in popularity recently as it is the simpler of the surgeries for chronic pancreatitis and has fewer associated complications.¹⁹³ It entails partial resection of the pancreatic head and a longitudinal pancreaticojejunostomy with a Roux loop (Fig. 99-8). This procedure should not be performed in the presence of a pancreatic or biliary stricture.¹⁸⁸ There is a reduced rate of postoperative complications, most notably, anastomotic leaks, compared with the Beger procedure.¹⁹⁴ In a study comparing this procedure with the Beger procedure, there was a tendency for better pain control with the Frey procedure. The functional outcomes of the two procedures in that study were almost identical. After this surgical procedure, a large cavity may be seen in the pancreatic head on CT; this should not be mistaken for a cystic fluid collection or neoplasm.¹⁸⁸

Beger Procedure

This procedure is less radical than a Whipple operation but is technically much more complex to perform; it is also significantly more complex than the Frey procedure.¹⁸⁸ The Beger procedure involves a complex extensive surgical resection, whereas the Frey procedure is a simpler decompressive surgery.¹⁹⁴ The Beger procedure is also associated with a higher percentage of complications.^{193,195} The pancreatic body and large part of the pancreatic head are resected. The duodenum is left intact along with a small portion of the adjacent pancreas with the intrapancreatic, choledochal, and ampullary structures; that preserves blood flow through the posterior branch of the gastroduodenal artery to the duodenum. As a result, there are two pancreaticojejunostomy sites with the Roux loop¹⁸⁸ (Fig. 99-8). In a study comparing this procedure with the Whipple procedure, improved pain tolerance and glucose control were noted with the Beger procedure.¹⁹⁶

Central Pancreatectomy

This procedure is mainly used in patients with traumatic pancreatic transection and intractable chronic pancreatitis. It has also been proposed for selective management of benign and low malignant potential lesions of the pancreatic neck. It consists of resection of part of the neck or body of the pancreas, followed by a Roux-en-Y pancreaticojejunostomy to the distal pancreatic remnant. The distal pancreatic end can also be anastomosed to the stomach. The proximal cut edge is sutured.

Whipple Operation

This procedure, also known as pancreaticoduodenectomy, is considered to be the standard procedure for resection of head lesions and carcinoma of the periampullary region; it entails resection of the distal stomach, duodenum, and either part or all of the pancreas.¹²² Total pancreatectomy (double Whipple) has the theoretical advantage of preventing local recurrence of the tumor but results in permanent diabetes and exocrine insufficiency. Also, this radical operation has not been proved to be associated with significantly increased survival.

The gastrointestinal tract must be reconstructed, which requires anastomosis of the jejunum to the pancreas

Figure 99-7 Puestow procedure. **A.** Color diagram of the expected anatomy after Puestow procedure. A long longitudinal incision throughout the main pancreatic duct is performed with anastomosis to a similarly opened Roux-en-Y loop of jejunum to create the longitudinal pancreaticojejunal anastomosis. Inset shows the anastomosis in cross section. **B.** CT scan obtained in a 41-year-old man during the arterial phase of contrast material enhancement shows the expected alterations in normal anatomy after a Puestow procedure. The collapsed pancreaticojejunal anastomosis (arrows) is immediately anterior to the body of the pancreas. D, Duodenum; GB, gallbladder. **C.** CT scan of the pancreatic tail in a 70-year-old man shows the Roux-en-Y loop (arrows) distal to the pancreaticojejunal anastomosis (arrowhead). The loop contains a small amount of oral contrast material and gas. (B and C from Freed KS, Paulson EK, Frederick MG, et al: Abdomen after a Puestow procedure: Postoperative CT appearance, complications and potential pitfalls. Radiology 203:790-794, 1997.)

(pancreaticojejunostomy), the biliary tract (usually the common hepatic duct; hepaticojejunostomy), and the stomach (gastrojejunostomy). This reconstruction also requires that the inflow of alkaline bile and pancreatic juice be inserted proximal to the gastrojejunostomy to further protect against marginal ulceration.^{122,182-189} Potential technical modifications of this procedure include performing a pancreaticogastrostomy instead of pancreaticojejunostomy along with the pancreaticoduodenectomy and the pyloric-preserving Whipple operation. In comparing pancreaticogastrostomy with pancreaticojejunostomy, overall postoperative complications and pancreatic fistulas occurred at the same rate; however, biliary fistula, postoperative collections, and delayed gastric emptying were reduced with pancreaticogastrostomy.¹⁹⁷ Another study, comparing the standard and pyloric-preserving Whipple procedure, showed similar overall outcomes including complication and survival rates in both patient groups.¹⁹⁸

On CT examinations, there are several findings related to the three surgical anastomoses of a Whipple operation that can serve as potential pitfalls in the interpretation of these postoperative scans.^{199,200} Accurate interpretation of these complex postoperative examinations requires knowledge of the type of surgery performed, including surgical anastomoses, the interval between surgery and imaging, and whether the patient has received any ancillary treatment such as radiation therapy or chemotherapy. Optimizing scanning techniques and a strong familiarity with the expected postoperative imaging findings are essential to the early detection of recurrent and metastatic disease and to avoid false-positive or false-negative interpretations²⁰¹ (Figs. 99-9 and 99-10).

The hepaticojejunostomy often will reflux air and sometimes contrast material in 80% of patients. The duodenojejunostomy or gastrojejunostomy can have a confusing appearance, depending on its position determined by the surgeon, generally

Figure 99-8 Frey and Beger procedures. **A.** Color diagram shows expected postsurgical changes after a Frey procedure. Partial resection of the pancreatic head is performed with a longitudinal pancreaticojejunostomy of the main pancreatic duct and Roux-en-Y jejunal loop. The arrow indicates the area of pancreatic head resection, which may appear as a large cavity on imaging. **B.** Color diagram shows the postsurgical anatomy after a Beger procedure. The pancreatic body and a smaller portion of the pancreatic head are resected. A portion of the pancreatic head, along with the duodenum, is left intact. This preserves the adjacent intrapancreatic choledochal and ampullary structures. Two separate pancreaticojejunostomy sites with the Roux-en-Y jejunal loop are created. (Medical illustration by David Botos, Northwestern University.)

Figure 99-9 Whipple procedure. **A.** Color illustration showing postoperative changes of the Whipple procedure. The duodenum, distal stomach, and pancreatic head are resected. Subsequent anastomosis of jejunum to the pancreas, biliary tree, and stomach is performed with the resultant afferent loop. **B.** Postoperative appearance after Whipple procedure on CT. Contrast-enhanced CT appearance of the pancreaticojejunostomy (arrow) in a 52-year-old woman who underwent Whipple operation for pancreatic cancer. Surgical clips are also seen in the gastric antrum, related to partial resection of the distal stomach. The gastrojejunostomy is not seen on this image. **C.** Normal pneumobilia after biliary-enteric anastomosis on CT. Air (arrow) is identified in nondependent left hepatic ducts on the contrast-enhanced CT scan. **D.** Normal pneumobilia after biliary-enteric anastomosis on ultrasound. Biliary air is seen as bright intrahepatic specular reflectors (short arrows) that cast an acoustic shadow (long arrow).

Figure 99-10 Follow-up imaging after Whipple procedure. **A.** Anastomotic breakdown. Contrast-enhanced CT in a 67-year-old woman on postoperative day 10 after Whipple procedure. There is dehiscence of the anastomosis at the afferent loop (*long arrow*) with a small collection of air (*short arrow*) and early abscess formation. Perihepatic free fluid is also present (*curved arrow*). **B.** Recurrent pancreatic cancer. Contrast-enhanced CT in a 57-year-old woman 8 months after Whipple procedure for pancreatic cancer. There is a soft tissue mass encasing the mesenteric vasculature (*short arrow*). The afferent loop (*long arrow*) has a normal appearance. Expected pancreatic body and tail atrophy is seen (*curved arrow*).

Figure 99-11 Afferent loop obstruction. Obstructed afferent loop caused by tumor recurrence after Whipple procedure for carcinoma of the pancreatic head. **A.** Barium study shows an antiperistaltic Billroth II gastrojejunostomy. The efferent loop (EL) fills normally. The distal portion of the afferent loop (AL) is also opacified. **B.** CT scan at the level of the pancreas shows the dilated afferent loop. The pancreatic duct (*arrows*) is dilated as well. **C.** More caudal scan shows the dilated afferent loop and tumor recurrence (*arrows*). **D.** Afferent loop dilation and retention of contrast medium were confirmed by endoscopic retrograde pancreatography.

antecolic in the left upper quadrant. Sometimes, the anastomosis can be positioned in a retrocolic fashion that lies adjacent to the superior mesenteric vein, simulating the duodenum, a lymph node, or recurrent tumor. The pancreaticojejunostomy may cause a soft tissue prominence that is secondary to surgical invagination of the pancreas into the bowel loop.¹⁹⁹ The pancreatic remnant usually atrophies to some degree, and the pancreatic duct becomes slightly prominent. Reactive lymph nodes and streakiness of the peripancreatic fat surrounding the superior mesenteric artery can simulate recurrent tumor. Common postradiation effects include thickening of the gastric antrum

or gastrojejunostomy; fatty infiltration of the liver; stranding of the mesenteric fat within the radiation port; and occasionally decreased function within the medial portions of the kidneys, depending on the depth of the radiation port.²⁰¹

It appears that the serum marker cancer antigen 19-9 is expressed by the majority of pancreatic cancers, and it may be able to suggest recurrences.^{202,203} Thus, serial postoperative CT scans should be obtained at 3- to 6-month intervals in conjunction with laboratory values because pancreatic neoplasms can recur quickly.²⁰⁴⁻²⁰⁶ Furthermore, PET/CT may have an important role in assessing the post-Whipple cancer patient.

In one study, PET/CT correctly detected local recurrence in all cases of recurrence in patients who had surgery, whereas MDCT alone detected the recurrence in 64% of cases. This was a relatively small study, and larger, more conclusive studies are needed.

Bypass Procedures

Cholecystojejunostomy or choledochojejunostomy is performed to bypass unresectable pancreatic head neoplasms. Contrast medium and intestinal gas (Fig. 99-9) will reflux into the biliary system as a result.²⁰⁷

POSTOPERATIVE COMPLICATIONS

Definitive or palliative surgery for pancreatic disease is fraught with the same complications that attend other abdominal operations: abscess, anastomotic leaks or strictures, and recurrent disease. Interpretation of imaging studies is difficult unless the radiologist is aware of the specific anatomic alterations produced by the surgery (Fig. 99-11). Pseudocysts and fluid collections are specific complications that may occur with pancreatic surgery, and they can be diagnosed and treated with ultrasound, CT, and MRI.²⁰⁸⁻²¹¹

Post-Transplantation Lymphoproliferative Disease

Conclusion

Pancreas transplantation offers patients with severe type 1 diabetes mellitus the ability to restore normoglycemia and to halt or reverse the progression of diabetic complications, such as nephropathy, retinopathy, and vasculopathy.^{1,2} The standard procedure is transplantation of a whole-organ cadaveric pancreas while the recipient's native pancreas is left in place. Surgical techniques are varied and have evolved during the last four decades. Despite improvements during this period in both patient and graft survival rates, graft loss occurs with high prevalence. Early detection of graft-related complications is fundamental for graft survival and often relies on multiple imaging modalities. Imaging after pancreas transplantation poses a special challenge to the radiologist because it requires knowledge of the transplantation procedure, the complex postsurgical anatomy, and a wide spectrum of postoperative complications. Ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI) offer specific advantages and limitations in this setting, and a multimodality approach is often required to optimally evaluate the pancreas transplant. In this chapter, we review the spectrum of surgical procedures, postoperative anatomy, and complications of pancreas transplantation with emphasis on the normal and abnormal findings seen at US, CT, and MRI.

Types of Pancreas Transplantation

According to the International Pancreas Transplant Registry, more than 26,000 pancreas transplantations have been

performed in the United States since 1988; 1042 were performed in 2012.³ Three types of pancreas transplantation procedures are typically performed. Most commonly, the pancreas is transplanted from a deceased donor together with a kidney transplantation occurring at the same time (simultaneous pancreas-kidney [SPK] transplantation); this accounts for 75% of pancreas transplants performed in the United States today.⁴ Less commonly (18% of cases), a patient receives a pancreas transplant after having already undergone successful kidney transplantation from a live or a deceased donor (pancreas after kidney [PAK] transplantation).⁴ Pancreas transplantation alone (PTA) is performed least commonly, accounting for 7% of cases.⁴

SPK transplants allow patients to be free of both insulin therapy and dialysis and result in higher 1-year graft survival rates (86%) than PAK or PTA transplants (80% and 78%, respectively).⁴ This difference persists in the long term, with SPK transplants demonstrating a graft function rate of 45% at 20 years compared with 16% for PAK and 12% for PTA transplants.⁵ The advantages of pancreas transplantation must be balanced against short-term surgical complications and long-term immunosuppressive regimens. However, with recent advances in surgical technique, human leukocyte antigen matching, and immunosuppressive regimens, all types of pancreas transplants have shown significant improvements in both patient and graft survival rates during the last two decades.^{4,6,7} Living donor pancreas transplants account for a small minority of cases (0.5%) and are not discussed.⁸

Pancreas Transplant Anatomy

PANCREAS PROCUREMENT

The pancreas allograft is harvested with its vascular support and a segment of the donor duodenum containing the ampulla of Vater. The donor's iliac artery bifurcation is also procured for reconstruction of the arterial conduit. Surgical techniques have evolved over time to deal with arterial inflow, venous outflow (endocrine secretions), and pancreatic duct exocrine drainage, with the most variability in the venous and duodenal attachments.

Arterial Supply

The pancreas transplant receives arterial inflow from two sources: the donor superior mesenteric artery, which supplies the head through the inferior pancreaticoduodenal artery; and the donor splenic artery, which supplies the body and tail.⁸⁻¹⁰ The internal and external iliac arteries of the donor iliac bifurcation are attached in an end-to-end fashion to the donor superior mesenteric artery and splenic arteries, forming a Y graft (Figs. 100-1 and 100-2). The common iliac portion is then anastomosed to the recipient common iliac artery or external

Figure 100-1 Posterior view of donor pancreas demonstrating vascular reconstruction. The donor iliac Y graft is attached to the donor splenic artery (SA) to supply the body of the pancreas and to the donor superior mesenteric artery (SMA) to supply the head of the pancreas through the inferior pancreaticoduodenal artery (arrowhead). The donor portal vein (PV) functions as the main graft vein and drains the donor splenic vein (SV) and donor superior mesenteric vein (SMV). The donor duodenal stump is harvested along with the pancreas (asterisk). (Copyright © 2015 Aletta Ann Frazier, MD. Published by Elsevier Inc. All rights reserved.)

iliac artery, with a variable graft length depending on the venous and duodenal attachments.

Venous Drainage

Venous outflow from the graft may be drained to the recipient's portal or systemic venous system. Pancreas transplantations were originally performed with systemic venous drainage. However, pancreatic endocrine secretions contained in the venous outflow raised concerns about systemic hyperinsulinemia causing accelerated atherosclerosis, hypertension, and hypercholesterolemia and resulted in a change to the more physiologic state of portal venous drainage.^{8,11-14} This is accomplished by grafting the donor portal vein, which functions as the main graft vein, to the recipient superior mesenteric vein (see Figs. 100-1 and 100-2A). Systemic venous drainage involves an anastomosis of the graft vein to the recipient iliac vein (see Fig. 100-2B) or, rarely, to the inferior vena cava. These techniques are currently equivalent in terms of patient and short-term graft survival, and although systemic drainage is currently predominant, portal venous drainage is still widely used.^{4,8,15}

Exocrine Secretions

Pancreatic exocrine secretions drain into the donor duodenal stump that is harvested with the pancreas. This can be attached side-to-side to the recipient's small bowel for enteric drainage or to the recipient's bladder. Enteric exocrine drainage is used

Figure 100-2 Anterior view of two types of pancreas transplants as seen through the overlying pancreas. **A.** Portal venous and enteric exocrine drainage. The graft artery (Y) is attached to the common iliac artery (arrowhead) proximally; the distal limbs are connected to the donor splenic artery (SA) and donor superior mesenteric artery (SMA). The graft vein (PV) is attached to the recipient superior mesenteric vein (arrow) for portal venous drainage. The donor splenic vein (SV) and donor superior mesenteric vein (SMV) are demonstrated as well. Exocrine drainage is achieved through the pancreatic duct (PD) draining to the duodenal stump (asterisk), which is anastomosed to the jejunum. IVC, Inferior vena cava; Ao, aorta. **B.** Systemic venous and bladder exocrine drainage. The graft artery (Y) is attached to the common iliac artery (arrowhead) proximally; the distal limbs are connected to the donor splenic artery (SA) and donor superior mesenteric artery (SMA). The graft vein (PV) is anastomosed to the recipient external iliac vein (arrow), providing systemic venous drainage of the donor splenic vein (SV) and the donor superior mesenteric vein (SMV). Exocrine secretions are drained through the pancreatic duct (PD) to the duodenal stump (asterisk), which is anastomosed to the bladder (Bl). (Copyright © 2015 Aletta Ann Frazier, MD. Published by Elsevier Inc. All rights reserved.)

most commonly (91% of SPK, 89% of PAK, 85% of PTA), with or without the creation of a Roux-en-Y loop (see Fig. 100-2A).⁴ Enterically drained transplants are usually located in the midabdomen to the right of midline, with the head of the pancreas situated cranially for portal venous drainage or caudally for systemic venous drainage. Bladder drainage of exocrine secretions is achieved by an anastomosis between the donor duodenal stump and the superior aspect of the bladder (see Fig. 100-2B). Bladder-drained allografts are usually located in the right pelvis, superior to the bladder, with the head of the pancreas directed caudally. One advantage of bladder drainage is that urinary amylase may be used to monitor graft function. However, in many centers, enteric drainage is preferred to bladder drainage because it is associated with fewer metabolic complications and lower rates of hematuria and recurrent urinary infections.¹⁶ Enteric conversion may be successfully performed after initial bladder drainage; up to 25% of patients undergo this procedure.⁸

Pancreas Transplant Imaging: Normal Appearances

ULTRASOUND

US is the most commonly used imaging modality to evaluate the transplanted pancreas; it is routinely used in its initial evaluation.¹⁰ Gray-scale imaging can demonstrate the allograft and peripancreatic fluid collections; color and duplex Doppler imaging can document perfusion and evaluate the arterial and venous vasculature.^{9,10} The well-known advantages of US include availability, repeatability, and portability for ill and unstable patients in the postoperative setting. US can also be used to guide percutaneous biopsy of the transplant pancreas. Sonographic evaluation is, however, operator dependent, and anatomic challenges, such as obscuration by bowel, are not uncommon. Unless it is abnormally dilated, the duodenal component most often cannot be separately evaluated. When direct visualization of the transplant pancreas is difficult, color and power Doppler imaging can help in identifying parenchymal and graft vessel flow, thereby localizing the pancreas.

The normal pancreas transplant is a homogeneous soft tissue structure hypoechoic relative to surrounding mesenteric fat on gray-scale US (Fig. 100-3A).^{10,17} Because it lacks a capsule, its borders may be indistinct, and it may be difficult to distinguish the allograft from adjacent structures. Color and power Doppler are essential to demonstrate pancreas transplant perfusion and vascular anatomy; the Y arterial graft, graft vein, and splenic artery and vein are usually visible (Fig. 100-3B-D). Arterial waveforms normally show a rapid systolic upstroke and continuous diastolic blood flow, whereas venous structures demonstrate a monophasic waveform within an anechoic lumen (Fig. 100-3E). Arterial resistive indices are variable within the graft and are not useful in distinguishing normal from abnormal grafts.^{18,19}

COMPUTED TOMOGRAPHY

CT is most often performed when there is concern for abdominal infection, bowel complication, or pancreatitis or its complications. It is better suited to evaluate fluid collections and bowel complications because of its wider field of view and intrinsic properties.¹⁷ CT can reliably demonstrate the pancreas, the

duodenal stump, and the recipient small bowel, which can be useful when the transplant cannot be visualized sonographically because of overlying bowel gas. This may be particularly helpful in guiding percutaneous biopsy.

Positive enteric contrast agents should be used to differentiate bowel from fluid collections and from the transplant. Because most allografts are SPK transplants, CT is usually performed without intravenous contrast material to avoid further renal injury in patients with impaired renal function. This limits evaluation of the vasculature and parenchymal enhancement. On unenhanced CT, the allograft appears as a homogeneous soft tissue structure that may be isodense to and difficult to distinguish from unopacified and nondistended bowel, although surgical staples on either side of the duodenal stump are helpful for localization (Fig. 100-4A). The donor duodenum is often collapsed and thick walled but can be misinterpreted as a fluid collection when it is distended. It inconsistently opacifies with oral contrast material even when the adjacent jejunum is contrast filled. Contrast-enhanced CT, especially with multiplanar reformations, can demonstrate the vascular anatomy and parenchymal enhancement well (Fig. 100-4B, C).

MAGNETIC RESONANCE IMAGING AND ANGIOGRAPHY

MRI and magnetic resonance angiography (MRA) are used less frequently in the evaluation of the transplanted pancreas. They are most commonly performed to confirm the diagnosis of a vascular complication, after an abnormal or nondiagnostic US or CT study. High-resolution, three-dimensional (3D), contrast-enhanced MRA provides an accurate diagnostic technique for evaluation of the arterial and venous anatomy of the pancreas transplant.^{17,20-22} Unenhanced MRI sequences readily separate the pancreatic allograft from adjacent structures and are superior to CT without intravenous contrast material. MR is particularly useful when US is limited by overlying bowel gas or by body habitus. Given the increased risk for nephrogenic systemic fibrosis in patients with end-stage renal disease, the risk/benefit ratio of intravenous gadolinium-based contrast agents should be carefully assessed. Unenhanced MRA is unlikely to perform as well as contrast-enhanced MRA, but it has not been formally evaluated in this setting.

On T1-weighted images, the pancreatic parenchyma is homogeneous and hyperintense relative to the liver. On T2-weighted images, the normal pancreas allograft will show signal intensity between fluid and muscle (Fig. 100-5A). T2-weighted images are most sensitive to abnormalities of the pancreatic transplant because the majority of pathologic processes increase glandular water content. We typically use a coronal 3D fat-suppressed breath-hold gradient-echo T1-weighted dynamic enhanced sequence to demonstrate the arterial and venous anatomy and parenchymal enhancement (Fig. 100-5B). The data set can be used to generate 3D maximum intensity projection or volume-rendered images to optimally evaluate the vasculature (Fig. 100-5C).

Pancreas Transplant Imaging: Postoperative Complications

Despite steady improvements in patient and graft survival rates, graft failure remains a problem after pancreas transplantation.

Figure 100-3 Normal US appearance of pancreas transplant in different patients. **A.** Longitudinal gray-scale image of the head (HOP), body (BOP), and tail (TOP) of a pancreas allograft shows a well-defined, homogeneous hypoechoic structure. **B.** Color Doppler image of the vascular pedicle demonstrates flow within the patent donor Y-graft artery (curved arrow) bifurcating into the splenic artery (arrow) and superior mesenteric artery (arrowhead). **C.** Color Doppler image of venous drainage of the pancreas transplant shows the confluence of the donor splenic vein (long arrow) and donor superior mesenteric vein (arrowhead) forming the portal vein (curved arrow). Note echogenic foci representing venous anastomotic site (short arrows). (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.) **D.** Longitudinal color Doppler image shows normal parenchymal perfusion. **E.** Spectral Doppler imaging through the body of the allograft demonstrates normal low-resistance arterial waveform of the splenic artery.

The causes of graft failure vary by the time since transplantation and the type of transplant. In the first 6 months after transplantation, most complications are due to surgical or technical failure, more than 55% in all categories of transplants.²³ Technical failure occurs in 7% to 9% of cases and includes thrombosis, infection, pancreatitis, anastomotic leak, and bleeding leading to removal.²⁴ Repeated laparotomy rates remain high for all types of transplants, up to 35%.^{24,25} Nonsurgical complications are usually immunologic, with rejection being the single most common cause of graft loss. Acute rejection peaks between 3 and 12 months, whereas graft loss due to chronic rejection increases at a constant rate over time.^{23,26} Primary nonfunction occurs in 0.5% to 1% and is defined by the exclusion of other causes of early graft failure.²⁴

VASCULAR COMPLICATIONS

Graft Thrombosis

Acute graft thrombosis is the most frequent and serious technical cause of graft failure in the early postoperative period, occurring in 2% to 10% of patients, typically in the first 6 weeks after surgery.^{24,25} Venous thrombosis is more common than arterial and accounts for the second most common cause of overall graft failure after rejection.^{27,28} Acute vascular thrombosis can be manifested with hyperglycemia, abnormal levels of amylase, graft tenderness, and swelling with hematuria, if the transplant is bladder drained. Thrombectomy and thrombolysis have a limited role in management, confined to short-segment thrombosis without necrosis.²⁴ Prompt pancreatectomy is

Figure 100-4 Normal CT appearance of pancreas transplant in different patients. **A.** Coronal maximum intensity projection image from unenhanced CT shows surgical staple lines (arrows) along the duodenal stump (asterisk), aiding localization of the pancreas transplant (arrowhead). **B.** Coronal multiplanar reconstruction image shows a patent graft vein (arrow) with normal parenchymal enhancement of the pancreatic body and tail (arrowhead). **C.** Coronal anterior oblique 8-mm maximum intensity projection image from an enhanced CT study of a bladder-drained left lower quadrant pancreas allograft transplanted after a renal transplant (K) shows surgical staple lines (arrows) along the lateral margins of the duodenal stump, which aids in the identification of the duodenocystostomy (asterisk). The pancreas transplant (arrowhead) is readily identified with normal parenchymal enhancement. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-5 Normal MR appearance of pancreas transplant in different patients. **A.** Coronal half-Fourier acquisition single-shot turbo spin-echo (HASTE) T2-weighted MR image shows the pancreas transplant (curved arrow), which has signal intensity between that of muscle and fluid. A nondilated segment of pancreatic duct is visible (arrowhead). **B.** Coronal dynamic volume-interpolated breath-hold examination (VIBE) shows normal enhancement of the pancreas transplant (arrowhead), with a patent graft vein (arrow) draining into the recipient's superior mesenteric vein (asterisk). Note the normally enhancing left lower quadrant renal transplant. **C.** Maximum intensity projection shows a patent Y-graft artery (curved arrow) anastomosed to the right common iliac artery. Note the splenic (arrow) and superior mesenteric (arrowhead) branches. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

usually required because early pancreatectomy decreases infectious complications and mortality.

The etiology of thrombosis is multifactorial. The pancreas has a smaller microcirculatory blood flow than other allografts, resulting in an increased propensity to thrombosis. Contributory donor factors include donor obesity and cardiovascular disease, back-table preparation, and cold ischemia time.²⁷ Thrombosis occurs more often in PAK and PTA grafts than in SPK transplants and more often with enteric than with bladder drainage.^{8,26} Severe pancreatitis, arterial wall injury, and development of stump thrombi also place the patient at risk.^{20,29,30} When the pancreas is harvested, vascular stumps are created within the peripheral superior mesenteric and splenic arterial and venous segments (see Figs. 100-1 and 100-2). Stagnant blood may clot in these low-flow areas and result in stump thrombi. Short-segment peripheral splenic vein thrombi can be seen incidentally and may not interfere with graft functioning. Full anticoagulation is usually instituted to prevent clot propagation; thrombolysis has also been attempted. Many centers use prophylactic anticoagulation perioperatively with attendant increased risks of bleeding.²⁴

Graft thrombosis after the early postoperative period may also be the result of acute or chronic graft rejection, in which an autoimmune vasculitis and fibrosis cause the gradual occlusion of small and large vessels. Extensive thrombosis usually causes parenchymal necrosis, requiring urgent pancreatectomy.²⁷ Rarely, after total arterial Y-graft thrombosis, collateral vasculature may preserve some pancreatic function and parenchyma.

US findings of vascular thrombosis depend on the degree and location of the clot.^{17,30} These include echogenic intraluminal thrombus on gray-scale imaging and absence of vascular flow in the vessel and possibly throughout the parenchyma at color and pulsed Doppler imaging (Figs. 100-6A and 100-7A). With venous thrombosis, arterial waveforms typically show a high-resistance pattern with reversal of diastolic flow (Fig. 100-6B). If pancreatic infarction results, the transplant will appear enlarged and hypoechoic without color flow (Fig. 100-6A). With chronic thrombosis, the allograft may be

atrophic and difficult to see with US. It is typically increased in echogenicity with decreased perfusion.

Thrombosis cannot be excluded with CT unless intravenous iodinated contrast material is used. However, acute thrombus may be suspected on unenhanced CT as a subtle, high-density tubular abnormality, typically prompting confirmation with US, MRI, or MRA. Conventional angiography has a limited role in the diagnosis of graft thrombosis but may be combined with thrombolysis in highly selected cases.

Multiphasic 3D contrast-enhanced MRA can be used after nondiagnostic or inconclusive sonography; MRA is a reliable method for identifying vascular complications of occlusion, stenosis, and infarction.²⁰⁻²² After contrast enhancement, thrombus may be visualized as a hypointense intraluminal filling defect, and the degree of pancreatic enhancement can be assessed (Figs. 100-7B, 100-8, and 100-9A,B). In complete infarction, the pancreas transplant shows high T2 signal intensity and absence of enhancement. T1 signal intensity may also be increased in hemorrhagic infarction.

In the much less common setting of chronic thrombosis, collateral vessels may produce peripheral rim enhancement around the otherwise nonenhancing pancreas (see Fig. 100-8B).

In patients with renal failure and decreased creatinine clearance, in whom gadolinium-based contrast agents are avoided because of the risk for nephrogenic systemic fibrosis, unenhanced MRI may be adequate for vascular evaluation. Although parenchymal enhancement cannot be evaluated without contrast material, thrombus may be detected as increased T1 signal or lack of flow void in the vessels (Fig. 100-9C). TrueFISP (true fast imaging with steady-state free precession) or gradient-echo/time-of-flight sequences can be particularly useful in demonstrating abnormal low signal intensity in the thrombosed vessel (Fig. 100-9D).

Graft Stenosis

Stenoses can develop at any anastomotic site but are not common.³¹ Many recipients have peripheral vascular disease, and vascular inflow to the allograft may become compromised

Figure 100-6 Splenic vein thrombosis, requiring explantation on postoperative day 3, in a 35-year-old man after SPK transplantation.

A. Color Doppler US shows striated echogenic material distending the splenic vein (arrow) with no blood flow in the vessel or within the pancreatic allograft. **B.** Arterial waveforms obtained in the graft artery demonstrate a very high resistance waveform with reversal of diastolic flow. (From Vandermeer F, Manning MA, Frazier A, et al: Imaging of whole-organ pancreas transplants. *RadioGraphics* 32:411–435, 2012.)

Figure 100-7 Splenic vein thrombosis in a 48-year-old man after SPK transplantation. **A.** Longitudinal color Doppler US of the pancreatic tail shows a distended splenic vein containing intraluminal thrombus (arrow). **B.** Postcontrast fat-suppressed T1-weighted coronal MR image confirms the splenic vein thrombus (arrowhead) but also demonstrates normal gland enhancement (arrow). (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-8 Chronic arterial graft thrombosis due to chronic rejection in a 53-year-old woman. **A.** Subtracted MRA shows the stump (arrow) of the occluded graft artery. **B.** Coronal postcontrast fat-suppressed T1-weighted MR image shows that the pancreas (arrow) is largely infarcted with rim enhancement. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-9 Chronic arterial graft thrombosis in a 45-year-old woman after two failed pancreas transplants. **A.** Axial gadolinium-enhanced fat-suppressed T1-weighted MR image demonstrates no intraluminal opacification in the graft artery (arrow). **B.** Coronal oblique maximum intensity projection image derived from data acquired 3 minutes after the initial injection shows loss of intraluminal signal within the graft artery (arrow) just distal to the anastomosis with the right common iliac artery (curved arrow). Note the normally enhancing left lower quadrant renal transplant. **C.** Axial fat-suppressed T1-weighted image demonstrates high signal thrombus (arrow) in the graft artery. **D.** Axial TrueFISP MR image shows absence of normal high signal in the graft artery compatible with occlusion (arrow). (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

by atherosclerotic plaques. Stenoses may be detected at US by finding high velocity or turbulence at an anastomosis but are generally confirmed with MRA or conventional angiography.^{20,22} These may be suitable for endoluminal therapy.

Extrinsic compression or kinking of a vascular segment may mimic thrombosis on imaging. This can be seen when longer Y grafts are required to appropriately position portal-enteric transplants higher in the abdomen; these may kink or twist, resulting in another cause of vascular stenosis (Fig. 100-10).²² This condition may be identified only intraoperatively during planned explantation for presumed thrombosis.¹⁷

Pseudoaneurysm and Arteriovenous Fistula

Pseudoaneurysms or arteriovenous fistulas are uncommon postsurgical complications after pancreas transplantation. They may arise at a vascular anastomosis or biopsy site or in the

setting of infection or pancreatitis.¹⁷ Although usually asymptomatic, they are associated with a high risk of hemorrhage and a high incidence of graft loss.³² Pseudoaneurysms can mimic a postoperative fluid collection with gray-scale US. Duplex Doppler imaging and MRA best demonstrate these vascular complications.^{10,17,21,22,30}

US of a pseudoaneurysm shows a rounded structure on gray-scale imaging, with internal swirling blood flow on color Doppler imaging and a characteristic to-and-fro waveform in the neck, communicating with an adjacent artery.^{10,17,30} On contrast-enhanced MRA, the pseudoaneurysm fills with contrast material and may be variable in size.³³ Arteriovenous fistulas are variable in size and may not be visible on gray-scale images. Color Doppler imaging shows color aliasing and a characteristic high-velocity low-resistance Doppler waveform with pulsatile flow in the draining vein if it is large (Figs. 100-11 and

Figure 100-10 Pancreas transplant with portal venous–enteric drainage, initially placed in the right abdomen with the head of the pancreas directed cephalad, in a 25-year-old woman. Coronal gadolinium-enhanced T1-weighted VIBE MR image demonstrates twisting of the elongated graft artery (arrow), which is anastomosed to the right common iliac artery. Thrombosis (arrowhead) is seen just distal to the twisted segment. The tail of the pancreas allograft (curved arrow) has migrated from the right lower quadrant into the left upper quadrant. Note persistent but decreased enhancement of the allograft; areas of pancreatic infarction were identified during surgical exploration, necessitating explantation. Incidentally shown is normal arterial and venous supply of the normally enhancing left lower quadrant renal transplant. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

100-12).³⁰ Contrast-enhanced CT or MRI may show early opacification of donor venous structures during arterial phase imaging. Management of these vascular complications depends on the anatomy and size; small fistulas after biopsy may be self-limited and managed conservatively. Endovascular or surgical approaches are required otherwise.^{32,33}

GRAFT REJECTION

Rejection continues to be the overall primary cause of graft loss, with rates between 5% and 25%, depending on immunosuppressive regimen.⁸ Acute rejection has decreased dramatically with recent immunosuppressive advances, although less so with PTA transplants than with SPK or PAK grafts.³⁴ Because chronic rejection has been less affected by these advancements, this remains the major long-term cause of graft failure after the first 6 months, with little long-term improvement in pancreas survivability.³⁵

Figure 100-11 Iatrogenic arteriovenous fistula following biopsy in a 42-year-old woman after PTA. Longitudinal color Doppler sonogram shows a dilated tubular structure with turbulent flow closely associated with the transplant splenic vein and graft artery compatible with an arteriovenous fistula (AVF) within the proximal body of the pancreas (BOP). TOP, Tail of pancreas. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Graft rejection can occur at any time after pancreas transplantation. Hyperacute rejection, a rare occurrence, develops immediately after transplantation in response to the presence of preformed circulating cytotoxic antibodies in the recipient's blood. It causes thrombosis and immediate graft loss. Acute rejection usually develops 1 week to 3 months after transplantation and results in a peak in graft loss between 3 and 12 months.³⁶ Early detection is essential to institute antirejection treatment and to avert graft failure. Acute rejection is an autoimmune vasculitis that results in small-vessel occlusion and decreased perfusion, leading to infarction if it is severe and untreated. Multiple episodes of undiagnosed or partially treated acute rejection may culminate in chronic rejection with fibrosis and atrophy of the gland, resulting in insidious, progressive loss of graft function.¹⁸ The clinical diagnosis of rejection is difficult as elevation of serum glucose, amylase, and lipase levels correlates poorly with the presence or degree of rejection. Graft tenderness may be present. In bladder-drained pancreas transplants, urinary amylase and lipase levels may be abnormal. Percutaneous biopsy is therefore the cornerstone for diagnosis and grading of rejection. With a simultaneous pancreas and kidney transplant from the same donor, rejection of the kidney transplant may be used as a surrogate for pancreas rejection and monitored by serum creatinine concentration and renal biopsy.

US has a limited role in detecting acute rejection. Sonographic findings of graft enlargement and increased heterogeneity of the parenchymal echotexture lack specificity and may also be seen with acute pancreatitis and ischemia (Fig. 100-13).^{10,17} Color Doppler US usually demonstrates major vessel patency, which excludes graft thrombosis as a cause of poor function but cannot differentiate pancreatitis from rejection. Resistive indices have not been useful in diagnosis of acute rejection.^{18,37} In practice, the major role of US is to exclude thrombosis and to guide biopsy (Fig. 100-14). Severe acute rejection or hyperacute rejection may culminate in vascular thrombosis and infarction and be mistaken for primary

Figure 100-12 Iatrogenic arteriovenous fistula between donor superior mesenteric artery and donor portal vein in a 29-year-old woman 2 weeks after SPK transplantation. **A.** Duplex Doppler US image of a large vessel in the head of the pancreas shows a high-velocity, low-resistance waveform typical of an arteriovenous fistula (AVF). **B.** MRA demonstrates a dilated graft artery (arrow) and superior mesenteric vein (curved arrow). Focal narrowing of the distal vein graft (arrowhead) proximal to the anastomosis is also seen (asterisk, pancreas transplant). **C.** Selective arteriography confirms the fistula and better demonstrates an associated venous outflow stenosis (arrowhead). The fistula was embolized, but explantation of the allograft was subsequently performed for sepsis (arrow, dilated graft artery; curved arrow, dilated graft vein). (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-13 Acute rejection in a 30-year-old woman 7 months after PTA. Gray-scale US image shows an enlarged, hypoechoic allograft reflecting nonspecific edema that could be due to acute rejection, acute pancreatitis, or ischemia.

thrombosis. However, irrespective of the cause of thrombosis, management is surgical in these instances.

Unenhanced CT also offers limited utility in the diagnosis of acute rejection, demonstrating nonspecific gland enlargement, sometimes with peripancreatic fluid and duodenal edema, identical to findings seen with acute pancreatitis (Fig. 100-15). With iodinated contrast agents, the allograft is much more conspicuous and the vascular supply is optimally demonstrated, excluding thrombosis. However, decreased or heterogeneous enhancement resulting from occlusion of small graft vessels may be present.

At MRI, allograft edema from acute rejection can be recognized by increased T2 signal intensity; but this is nonspecific, and other causes of increased T2 signal include acute pancreatitis and ischemia. There may be a significant difference in enhancement between rejecting and normal pancreas allografts; however, this finding is only moderately specific.³⁸

With no reliable imaging modality to confirm or to grade acute rejection, image-guided percutaneous biopsy is the “gold standard.”³⁹ Although biopsy is most often performed with US guidance, CT-guided biopsy may be necessary when bowel obscures the anterior approach.

Chronic rejection occurs in 4% to 10% of patients.⁸ It is manifested as progressive loss of exocrine and then endocrine function secondary to small-vessel endarteritis, acinar atrophy, and interstitial fibrosis. This causes marked pancreatic atrophy, with the end result being a shrunken or disappearing pancreas transplant (Fig. 100-16). The demonstration of a small enhancing structure with patent graft vasculature at contrast-enhanced MRA confirms the diagnosis. Severe chronic rejection may ultimately result in infarction and necrosis from long-standing small-vessel occlusion with high signal seen on T2-weighted imaging (Fig. 100-17).

GRAFT PANCREATITIS

Mild, self-limited, and subclinical pancreatitis is common in the immediate postoperative setting; prolonged elevation of serum amylase occurs in up to 35% of patients.^{24,25} This usually results from reperfusion injury related to impaired microcirculation. Risk factors relate to donor age and preservation methods, including solution volumes, cold ischemia preservation time, and handling of the organ during surgery.^{24,40} Clinically significant pancreatitis occurs in 10% of patients.³¹ Symptoms include graft tenderness, abdominal pain, nausea,

Figure 100-14 US-guided percutaneous biopsy of the pancreas transplant. Transverse image obtained during a biopsy shows the 18-gauge core biopsy needle within the tail of the pancreas transplant.

vomiting, and ileus. Increased rates are seen with the bladder drainage technique.²⁴

The imaging appearance of the pancreatic graft may be normal with mild pancreatitis. More severe episodes may result in nonspecific enlargement and heterogeneity of the graft (Figs. 100-18 and 100-19). There may be perigraft fluid or mural thickening of adjacent bowel loops. Doppler US should demonstrate parenchymal flow in the transplant, unless the complication of pancreatic necrosis develops. US can demonstrate complications of pancreatitis, including pseudocyst or abscess formation and pancreatic infarction or necrosis. However, CT and MRI are more sensitive for peritransplant collections (see Fig. 100-19). The higher contrast resolution capability of MRI may best demonstrate the graft edema and potential complications, including vascular thrombosis.

HEMORRHAGE

Intra-abdominal hemorrhage is one of the most common reasons for relaparotomy after pancreas transplantation; however, it is an infrequent cause of graft loss.^{4,24} Bleeding may develop after any intra-abdominal surgery as a result of perioperative anticoagulation. If significant hemoperitoneum persists after correction of the coagulation profile, surgical evacuation is necessary to clear out potential medium for infection and can be therapeutic in itself.²⁴ Hemorrhage can also occur at vascular, bladder, or enteric anastomoses or secondary to an arterioenteric fistula.²⁴ Intravesical hemorrhage can be seen in bladder-drained transplants and may be early or late, potentially requiring enteric conversion.²⁴ Expedient evaluation should include CT and possibly conventional angiography. Unenhanced CT can best demonstrate intra-abdominal hemorrhage as a hyperdense collection.

Figure 100-15 CT appearance of nonspecific pancreas transplant edema, later shown to be acute rejection on biopsy. Unenhanced axial CT image demonstrates the pancreas transplant (arrow) as an ill-defined soft tissue structure in the right lower quadrant, difficult to distinguish from unopacified small bowel in the absence of intravenous contrast material but identified by duodenal stump suture lines (curved arrows). There is a small amount of adjacent free fluid (arrowhead). (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

BOWEL COMPLICATIONS

A review of bowel complications after pancreas transplantation showed a rate of 19.4%.⁴¹ These include small bowel obstruction, anastomotic leak, abscess, and pseudomembranous or cytomegalovirus colitis. CT should be performed when clinical findings suggest a bowel complication or abdominal infection. Early diagnosis is important in these immunosuppressed recipients to decrease mortality and morbidity.

Small Bowel Obstruction

Small bowel obstruction can occur as a result of adhesions after any major abdominal procedure; however, the intra-peritoneal placement of an enterically drained pancreas allograft through a mesenteric defect adds an additional risk factor for internal herniation. The rate of strangulation is higher with an internal hernia than with an adhesive small bowel obstruction. Therefore, internal herniation should be suspected in the context of obstruction. An internal hernia can be detected at CT by finding distended loops of distal small bowel posterior to the transplant or donor duodenum.⁴¹ Contrast opacification of the duodenal stump may indicate more distal bowel obstruction or may be normal. Small bowel obstruction resulting from adhesions tends to occur in the anterior abdomen and is usually low grade.⁴¹ CT with multiplanar reformations is the best imaging modality for this complication.

Figure 100-16 Chronic rejection in a 40-year-old man, 10 years after PAK transplantation. **A.** Transverse gray-scale US shows an atrophic echogenic pancreatic head (calipers) difficult to distinguish from mesenteric fat. **B.** Unenhanced CT image obtained before a CT-guided biopsy. Because the pancreas transplant (arrow) was small and difficult to separate from bowel, a biopsy could not be performed. **C.** Contrast-enhanced MRA showed a patent graft artery (not shown) and enhancing parenchyma (arrow) in the right lower quadrant. Note the enhancing left lower quadrant renal transplant. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-17 Chronic rejection and necrosis in a 42-year-old man after PTA 8 years earlier. **A.** Color Doppler US over an area of tenderness in the right iliac fossa shows a nonvascular ill-defined fluid collection (arrow) with no identifiable pancreatic tissue. **B.** Unenhanced CT shows loss of definition of tissue planes with fluid and gas (arrow) in the same area. **C.** Coronal HASTE T2-weighted MR image shows a high signal fluid collection (arrow) in the right lower quadrant and edema of the subjacent musculature. **D.** Postcontrast fat-suppressed T1-weighted axial MR image shows the rim-enhancing fluid collection (arrow) and inflammation of the iliacus and psoas muscles. At surgery, there was a purulent phlegmon and no recognizable pancreatic tissue. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-18 Postoperative pancreatitis after SPK transplantation in a 27-year-old woman. Longitudinal ultrasound image demonstrates an enlarged, hypoechoic transplant with surrounding fluid (arrowheads) and thickening of an adjacent bowel loop (arrow). HOP, head of pancreas; BOP, body of pancreas; TOP, tail of pancreas. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Anastomotic Exocrine Leak

Presenting symptoms and signs of an anastomotic leak include abdominal pain, fever, leukocytosis, peritonitis, and sepsis. Early leaks may be attributed to surgical factors, whereas late leaks are thought to result from infection, rejection, pancreatitis, or duodenitis.⁴²

Leaks occur in 2% to 10% of transplant patients after enteric drainage and predispose to intra-abdominal infection, which is the second most common cause of technical failure after vascular thrombosis.^{4,25} However, early recognition and appropriate management can minimize the impact of this complication on the patient's postoperative course. Anastomotic leaks are responsible for less than 0.5% of all graft losses,⁴³ with higher rates of loss for enterically drained grafts than for bladder-drained transplants.²⁴

Leaks in enterically drained transplants result in greater patient morbidity and mortality because of peritonitis and sepsis, which may result from the spillage of bowel contents from the leakage site, often the duodenojejunal anastomosis. Immediate surgical intervention with revision of the anastomosis is required.²⁴ For bladder-drained allografts, early leaks occur at the anastomosis to the bladder, and later leaks occur at the oversewn duodenal stump.^{24,25} Bladder leaks are less serious and may be managed by bladder catheterization. However, in the setting of peritonitis, repeated laparotomy is required, and conversion to enteric drainage is often necessary.

CT with oral contrast material is the modality of choice for diagnosis, although gas-containing collections may be detected at US (Fig. 100-20A, B). Leaks of duodenal secretions can be difficult to separate from other pancreatitis-related collections unless they contain gas. Oral contrast material should be administered to increase diagnostic confidence in distinguishing a leak from a collection. However, this can be of variable utility, given inconsistent filling of the duodenal bulb. An enterocutaneous fistula can result if a leak is not promptly diagnosed and treated (Fig. 100-20C). Leaks from bladder-

Figure 100-19 Pancreatitis with peripancreatic fluid collections in a 45-year-old woman after PAK transplantation. Coronal HASTE T2-weighted MR image shows a high signal fluid collection (arrowhead) surrounding and displacing the edematous transplant (asterisk) to the left and extending into the right lower quadrant. Note the wall thickening and edema of the adjacent bowel loop (arrow). The fluid collections eventually caused venous thrombosis and ultimately required explantation of the graft. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

drained transplants may be diagnosed by conventional cystography or CT cystography (Fig. 100-21).

Colitis

Pseudomembranous or cytomegalovirus colitis may be seen uncommonly after pancreas transplantation. CT with oral contrast material is the preferred imaging modality. However, appearances are not specific, and correlation with stool and blood evaluation is necessary.

INTRA-ABDOMINAL FLUID COLLECTIONS

Fluid collections are commonly seen after pancreas transplantation in the early and late postoperative course and can be detected by US, CT, or MRI. These may be clinically insignificant or associated with intra-abdominal infection. Ascites is not uncommon but usually low in volume. Surgical site infection may occur in up to 50% of patients, and most are superficial and managed with antibiotics and local care.²⁵ Deep infections are associated with higher morbidity, graft loss, and mortality, and after vascular thrombosis, they are the second leading cause of technical failure in the early postoperative period.⁴ Organisms include bacterial and fungal, and 50% of infections are diffuse. The clinical presentation and imaging findings are similar to those of an enteric leak, and in 30% there is an associated leak (see Fig. 100-20).²⁴ Localized abscesses may be managed by percutaneous drainage, but the threshold for laparotomy and washout is low (see Figs. 100-17 and 100-19).

Figure 100-20 Duodenal anastomotic leak in a 53-year-old man after systemic venous–enteric PAK transplantation. **A.** Color Doppler US image shows an avascular complex fluid collection lateral to the pancreas transplant (arrow) with echogenic foci (arrowhead) in the nondependent portion, suggesting the presence of gas. **B.** Unenhanced CT better shows the gas-containing complex peripancreatic fluid collection, closely associated with the duodenal suture line (arrow), which aids in localizing the pancreas transplant (arrowhead). **C.** Sinogram obtained after injection of contrast material through the existing pigtail drainage catheter shows opacification of a loop of small bowel compatible with a duodenal anastomotic leak. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Intra-abdominal collections could also represent seroma, hematoma, lymphocele, urinoma, or pseudocyst. Hematomas may be suspected by their internal echoes at US and higher density at CT (Figs. 100-22A, B and 100-23). MRI can also be helpful in identifying peripancreatic hematoma or hemorrhagic necrosis because of its bright T1 signal (Fig. 100-22C). However, the character of the fluid most often cannot be determined by the imaging appearance alone. Percutaneous US- or CT-guided aspiration is useful in diagnosis and therapeutic intervention. It is important to consider that a fluid collection adjacent to the head of the pancreas may be associated with the duodenum, possibly representing a dilated duodenal bulb or hematoma (see Fig. 100-23).

POST-TRANSPLANTATION LYMPHOPROLIFERATIVE DISEASE

Post-transplantation lymphoproliferative disease (PTLD) is a rare late complication after pancreas transplantation, occurring with an incidence of between 2.3% and 6%.^{34,44} PTA recipients experience a higher incidence of PTLD than SPK or PAK recipients do, probably related to their increased immunosuppressive requirements and higher rates of acute rejection.³⁴ Although the majority of cases are related to primary Epstein-Barr virus infection, cytomegalovirus infection and immunosuppression regimens are contributory. PTLD after pancreas transplantation may be more aggressive than

Figure 100-21 Anastomotic leak at the duodenocystostomy in a 53-year-old man 17 years after SPK transplantation with systemic venous–bladder drainage. Retrograde CT cystogram demonstrates leakage from the lateral margin of the duodenocystostomy (asterisk) adjacent to the duodenal suture line (arrow). The pancreas transplant (arrowhead) is more difficult to visualize because of lack of intravenous contrast material. Note the percutaneous pigtail drain in the right lower quadrant. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

in other solid organ transplants.⁴⁵ The mean time to diagnosis is 1.5 ± 0.5 years. Extranodal and widespread involvement is the hallmark of PTLD in pancreas transplant recipients and is present in 69%.⁴⁴ Lymph nodes and liver are the most frequent sites of involvement, in 39% to 40% of all PTLD patients, followed by the gastrointestinal tract in 33%.⁴⁵ The allograft is involved in 10%.⁴⁴

Disease extent is best imaged by CT or MR (Fig. 100-24), which may demonstrate solid masses in the liver and allograft and distribution of lymphadenopathy.⁴⁶ Hepatic involvement can be diffuse or multifocal. Bowel manifestations include focal masses, wall thickening, and dilation.

Conclusion

Diagnosis of postoperative complications after pancreas transplantation is often a complex process involving a multimodality approach and knowledge of the common surgical techniques and the spectrum of postoperative complications. US should be the first-line modality in evaluation of the pancreas allograft and vasculature. CT is useful in the evaluation of extra-allograft processes, particularly in ruling out abscess formation or evaluating for suspected bowel complication. MRI and MRA are reserved for transplants that cannot be completely evaluated by US or CT and for accurate assessment of vascular abnormalities.

The authors of this chapter published a comprehensive review of this topic with supplemental online material.⁴⁷ Images are reproduced from this article with permission from RadioGraphics.

Figure 100-22 Peripancreatic hematoma in a 44-year-old man after anticoagulation for partial splenic and superior mesenteric vein thrombosis in PAK transplantation. **A.** Longitudinal US shows a nonspecific hypoechoic avascular collection (arrows) with internal echoes posterior to the transplant pancreas and anterior to the right psoas muscle. **B.** Axial unenhanced CT demonstrates hyperdensity within the collection (arrows), suggestive of hematoma. **C.** On fat-suppressed T1-weighted MR image, there is characteristic high signal within the collection (arrows), confirming presence of blood products. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-23 Duodenal hematoma in a 31-year-old woman after systemic venous–enteric exocrine pancreas transplantation.

A. Longitudinal color Doppler image through the head of the pancreas demonstrates a focal avascular fluid collection containing internal echoes. **B.** Subsequent axial contrast-enhanced CT shows high-density material within the fluid collection (arrow), compatible with hematoma. Note normal enhancement of the pancreatic head (curved arrow) and patency of the graft artery (arrowhead) and graft vein (small arrowhead), which is anastomosed to the inferior vena cava. Given the location, adjacent to the pancreatic head, this was described as probable duodenal hematoma. On surgical exploration, the duodenum was found to be grossly necrotic, and although the pancreas was normally perfused and graft vessels were patent, the allograft was explanted. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

Figure 100-24 PTLD in two pancreas transplant recipients. **A.** Contrast-enhanced CT demonstrates rounded hypodense lesions in the liver (arrow) and spleen (curved arrow). **B.** Unenhanced CT in a different patient demonstrates a large necrotic mass arising from the small bowel and growing into the anterior abdominal wall (arrow). The pancreas transplant is not shown. Note bilateral renal transplants. (From Vandermeer F, Manning MA, Frazier A, et al: *Imaging of whole-organ pancreas transplants*. *RadioGraphics* 32:411–435, 2012.)

TABLE
101-1

Pancreatic Calcification

COMMON

Volume averaging with vascular calcification
Chronic pancreatitis
 Alcoholic (20%-50%)
 Hereditary (35%-60%)
 Biliary (2%)
 Idiopathic
Common bile duct stone

UNCOMMON

Acute pancreatitis with saponification
Serous cystadenoma (sunburst, 33%)
Mucinous cystadenoma or cystadenocarcinoma (rounded)
Pseudocyst
Islet cell tumor
Metastasis
Cystic fibrosis
Kwashiorkor
Cavernous lymphangioma
Adenocarcinoma (2%)
Intraparenchymal hemorrhage
Hyperparathyroidism
After infarct, abscess
After rupture of pancreatic neoplasm
Hemochromatosis

TABLE
101-2

Focal Pancreatic Mass

INFLAMMATORY

Acute pancreatitis
Chronic pancreatitis
Groove pancreatitis
Pseudocyst
Abscess

NEOPLASTIC—PRIMARY

Ductal adenocarcinoma
Intraductal papillary mucinous neoplasm
Islet cell tumors
Serous cystadenoma
Mucinous cystadenoma
Mucinous cystadenocarcinoma
Lymphoma
Metastases
Normal anatomic variant
Peripancreatic disease
Aneurysms
Thrombosed vessels

TABLE 101-3 Dilated Pancreatic Duct

Chronic pancreatitis
Pancreatic or ampullary mass
Distal common duct stone
Intraductal pancreatic mucinous neoplasm
Aging

NATURE OF DILATION**Suggesting Pancreatitis**

Irregular dilation
Calculi
Duct occupies >50% of anteroposterior gland diameter

Suggesting Neoplasm

Smooth and beaded appearance
Duct occupies >50% of anteroposterior gland diameter

TABLE 101-4 Gas in Pancreatic Duct

After endoscopic retrograde cholangiopancreatography
Prior papillotomy
Patulous Vaterian sphincter
Duodenal diverticulum
Enteropancreatic fistula (spontaneous, surgical)
Abscess

TABLE 101-5 Cystic Pancreatic Masses Within and Adjacent to Pancreas Pseudocyst

Cystic biliary and pancreatic duct anomalies
After inflammation
After trauma
After surgery
Idiopathic

CYSTIC NEOPLASMS

Ductal cancer
Cystadenoma
Cystadenocarcinoma
Leiomyosarcoma
Dermoid
Vascular
Lymphangioma
Hemangioma

RETENTION (POSTOBSTRUCTIVE)

Pancreatic cancer
Pancreatic lithiasis
Acute and chronic pancreatitis
Cholelithiasis and cholecystitis
Echinococcus infection
Ascaris infection
Clonorchis sinensis infection

CONGENITAL

Simple
Polycystic diseases
Cystic fibrosis
Duodenal enteric (duplication)
Intrapaneatic choledochal cyst
Cystic biliary and pancreatic duct anomalies

TABLE 101-6 Pseudocysts Versus Cystic Pancreatic Neoplasms: Differentiating Features

Feature	Cystic Neoplasm	Pseudocyst
Number of cysts	Multiple	Single
Common site	Body, tail	Head
Wall calcification	10%	Frequent
Wall thickness	>1 cm	<1 cm

TABLE 101-7 Pancreatic Lipomatosis

Obstruction of the main pancreatic duct
Age—atherosclerosis of elderly
Obesity
Steroid therapy
Cushing's syndrome
Cystic fibrosis
Shwachman-Diamond syndrome
Malnutrition
Hemochromatosis
Viral infection
Obstruction of the main pancreatic duct

Renal cell carcinoma
Adrenal carcinoma
Thyroid carcinoma

TABLE 101-11 Magnetic Resonance Pattern Recognition: Focal Pancreatic Lesions

Tumor Type	T1WI	T2WI	Early Gadolinium	Late Gadolinium	Imaging Comments
Ductal adenocarcinoma, small	↓	Ø	↓	↓-↑	Usually no background chronic pancreatitis, so tumor is well seen on precontrast T1WI
Ductal adenocarcinoma, large	↓-Ø	Ø-↑	↓	↓	Usually causes background pancreatitis, so tumor not well seen on precontrast T1WI Focal mass with definable margins shown on early postgadolinium images is the most common characteristic
Insulinoma	↓	↑	↑	Ø-↑	Tumors are usually < 1 cm
Gastrinoma	↓	↑	↑, Ring	Ø-↑	Tumors are usually in pancreatic head, and 50% have metastases at time of diagnosis. Liver metastases tend to be uniform, smooth, ring-enhancing tumors on immediate postgadolinium images that show peripheral washout.
Somatostatinoma	↓	↑	↑, Diffuse	Ø	Tumors are usually large at diagnosis, with most having liver metastases. Liver metastases are multiple with irregular ring enhancement and variable size.
Glucagonoma	↓	↑	Homogeneous	Heterogeneous	Primary tumor usually small at initial diagnosis with few varying size liver metastases with irregular ring enhancement
VIPoma	↓	↑	↑	Ø	Small cysts best seen on steady-state T2-weighted (SST2) sequences. Thin and regular septations. Septations may enhance on immediate postgadolinium images of larger tumors with thicker septations. Tumors may show a central scar that shows delayed enhancement.
Microcystic cystadenoma	↓	↑↑	Ø-↑	Ø	Septations of uniform thickness without mural irregularity or nodules
Macrocytic cystadenoma	↓	↑↑	Ø	Ø	Tumor may be locally aggressive with liver metastases. Liver metastases may have high signal on T1W1 due to high mucin content.
Macrocytic cystadenocarcinoma	↓	↑	Ø-↑	Ø-↑	

↓, Mildly decreased signal intensity; Ø, isodense; ↑, mildly increased signal intensity; ↑↑, moderately to markedly increased signal intensity.

Cholangiography

TABLE 101-12 Pancreatic Duct Stricture: ERCP or MRCP

Normal Parenchyma	Abnormal Parenchyma
Vascular compression	Carcinoma
Aneurysm	Chronic pancreatitis
Osteophyte	Duct hyperplasia

Imaging Findings in Specific Pancreatic Diseases

TABLE 101-13 Acute Pancreatitis

ULTRASOUND

Hypoechoic gland—diffuse (80%)
Hypoechoic mass—focal (20%); head or tail, not body
Peripancreatic fluid collection
Pseudocyst formation
Extrapaneatic hypoechoic mass—phlegmon
Dilation of the pancreatic duct if head is focally involved
Thick gallbladder wall

COMPUTED TOMOGRAPHY

Normal (29%)
Enlarged gland—diffuse (80%)
Enlarged gland—focal (20%)
Pancreas diffusely or focally hypodense
Hyperdense areas (50-70 HU) in hemorrhagic pancreatitis
Nonenhancing parenchyma in areas of pancreatic necrosis
Thickening of anterior pararenal fascia
Fluid collections in lesser sac, anterior pararenal space, posterior pararenal space, left subphrenic space, subperitoneal and interfascial spaces
Pseudocyst formation

MR IMAGING

Focal or diffuse enlargement
Heterogeneous appearance on precontrast T1-weighted fat-suppressed images
Heterogeneous diminished enhancement on immediate postgadolinium images
Hemorrhagic pancreatitis—high signal intensity on T1-weighted fat-suppressed images
Simple pseudocysts—low signal intensity on spin-echo and T1-weighted fat-suppressed images; high signal intensity on T2-weighted images

CHOLANGIOGRAPHY

Long, gently tapered narrowing of common bile duct
Prestenotic biliary dilation
Calculus in distal bile duct or common orifice

PLAIN ABDOMINAL RADIOGRAPH

“Colon cutoff” sign—dilated transverse colon with abrupt change to a gasless descending colon
“Sentinel loop”
“Renal halo” sign—water density of inflammation in anterior pararenal space contrasts with perirenal fat
Mottled peripancreatic region because of fat necrosis
Intrapaneatic gas bubbles
Gasless abdomen

UPPER GASTROINTESTINAL SERIES

Frostberg reverse 3 sign—reverse 3 contour to the medial portion of the duodenal sweep
Edematous swelling of papilla of Vater
Widened duodenal sweep with inferior displacement of the ligament of Treitz
Widened retrogastric space
Thick edematous folds of duodenum, gastric antrum, and greater curvature
Thickening of jejunal and ileal folds
Diminished duodenal peristalsis
Gastric and esophagogastric varices

BARIUM ENEMA

Narrowing, nodularity, and distortion along the inferior haustral row of the transverse colon
Stricture in region of hepatic flexure—proximal descending colon

TABLE 101-14 Chronic Pancreatitis

ULTRASOUND

Increased echogenicity of gland
Intraductal calcification
Atrophy
Focal or diffuse glandular enlargement
Pseudoaneurysm formation
Irregular pancreatic contour
Mild biliary ectasia
Splenic vein thrombosis and splenomegaly
Intrapaneatic and peripancreatic pseudocysts

COMPUTED TOMOGRAPHY

Small, atrophic gland
Fatty replacement of the parenchyma
Focal (12%-30%) or diffuse (27%-45%) pancreatic enlargement
Pseudoaneurysm formation
Intraductal calcification
Irregular pancreatic contour
Mild biliary ectasia
Splenic vein thrombosis and splenomegaly
Intrapaneatic and peripancreatic pseudocysts

MR IMAGING

Fibrosis—diminished signal intensity on T1-weighted fat-suppressed images and decreased, heterogeneous enhancement in immediate postgadolinium spin-echo images
Diminished enhancement in postcontrast capillary phase images because of disruption of normal capillary bed and replacement by less vascularized granulation tissue
Calcifications are manifested as a signal void.
Focal enlargement—cancer versus pancreatitis. Both show low signal intensity on noncontrast T1-weighted fat-suppressed and T2-weighted images. Postgadolinium image in focal pancreatitis shows heterogeneous enhancement with signal void cysts and calcifications, without a definable, minimally enhanced mass lesion. A definable, marginated mass suggests tumor.
Diffuse low signal intensity of the entire pancreas, including area of focal enlargement in T1-weighted fat-suppressed and immediate postgadolinium spin-echo images, is typical.
Ten percent show pseudocysts that are low signal intensity or signal void oval structures on T1-weighted images. They have signal intensity that varies on the basis of the presence of blood, protein, infection, and debris.

CHOLANGIOPANCREATOGRAPHY

Early: slight ductal ectasia with clubbing of side branches
Narrowing of the origins of side branches
Tortuosity, dilation, wall rigidity, main ductal stenosis (moderate disease)
“Beading,” “chain of lakes,” “string of pearls” sign in which dilation, stenosis, and obstruction of the main pancreatic duct and side branches (severe disease) are seen
Intraductal protein plugs and calculi
Prolonged retention of contrast material after endoscopic retrograde cholangiopancreatography
Stenosis with proximal dilation of the distal common bile duct

PLAIN RADIOGRAPHS

Numerous irregular calcifications

UPPER GASTROINTESTINAL SERIES

Displacement of the stomach or duodenum by a pseudocyst
Induration of gastric folds
Duodenal stricture

**TABLE
101-15****Pancreatic Ductal Adenocarcinoma****COMPUTED TOMOGRAPHY**

Focal mass (95%), diffuse enlargement (4%), normal scan (1%)
 Hypodense central zone in mass (75%-83%)
 Dilation of common bile duct and pancreatic duct
 Isolated dilation of bile duct or pancreatic duct
 Atrophy of pancreatic body and tail (20%)
 Postobstructive pseudocyst (11%)
 Obliteration of retroperitoneal fat (50%)
 Calcifications (2%)
 Dilation of common bile duct and pancreatic duct without a mass (4%)
 Invasion of perivascular lymphatics of celiac axis or superior mesenteric artery (60%)
 Local tumor extension into splenic hilum, into porta hepatis, or posteriorly (68%)
 Contiguous organ invasion of the stomach, duodenum, colon, greater omentum, mesenteric root, or transverse mesocolon
 Rounding of the uncinate process or other contour defect

ULTRASOUND

Hypoechoic pancreatic mass
 Contour deformity of gland and rounding of uncinate process
 Dilation of the common bile duct, pancreatic duct, or both

Mr Imaging

Low signal intensity on T1-weighted fat-suppressed images
 Rim of enhancement on immediate postgadolinium spin-echo images
 Intermediate signal intensity tumor, which invades low-intensity suppressed fat on gadolinium-enhanced fat-suppressed spin-echo images acquired 1-10 minutes after injection of contrast material
 Involved lymph nodes, which have moderate to high signal intensity in a background of low signal intensity suppressed fat on T2-weighted fat-suppressed spin-echo and interstitial-phase gadolinium-enhanced fat-suppressed T1-weighted images

ANGIOGRAPHY

Serrated, serpiginous, or smooth arterial encasement of the superior mesenteric artery (33%), splenic artery (14%), celiac trunk (11%), hepatic artery (11%), gastroduodenal artery (3%), left renal artery (0.6%)
 Venous obstruction: splenic vein (34%), superior mesenteric vein (10%)
 Venous encasement: superior mesenteric vein (23%), splenic vein (15%), portal vein (4%)
 Hypovascular tumor with neovascularity

CHOLANGIOGRAPHY

Irregular, nodular, "rat tail," eccentric stenosis of pancreatic duct
 Rat-tail or "nipple-like" obstruction of common bile duct
 Single or double obstruction of the common bile duct and duct of Wirsung
 Long, tapering stenosis with loss of lateral branches
 Loss of lateral branches with filling of a necrotic zone
 Abrupt occlusion of the main pancreatic duct
 Nonfilling of branches

UPPER GASTROINTESTINAL SERIES

Frostberg reverse 3 sign—reverse 3 contour to the medial portion of the duodenal sweep
 Antral "padding"—extrinsic indentation of the posteroinferior margin of the antrum
 Nodular mass in region of papilla with ampullary carcinoma
 Traction, spiculation, and fixation of the duodenal wall

BARIUM ENEMA

Serrated, flattened effect along inferior aspect of transverse colon and splenic flexure

**TABLE
101-16****Cystic Pancreatic Neoplasms****SEROUS CYSTADENOMA**

Well-demarcated, lobulated mass 4-25 cm in size (mean, 13 cm)
 Innumerable cysts <2 cm
 Prominent central stellate scar
 Amorphous central calcification (visible on plain film, 33%) in dystrophic area of scar
 Pancreatic and common bile duct that may be displaced, encased, or obstructed

Ultrasound

Complex, echogenic mass with internal echoes resembling a solid lesion; this is due to innumerable tiny cysts and dense radiating septa

Computed Tomography

Stellate septa
 Enhancement in the septa and cyst wall
 Honeycomb appearance

MR Imaging

Lobulated external border, especially on T2-weighted image with grapelike high-intensity cysts
 Multiple compartments with low signal intensity on T1-weighted image and high signal intensity on T2-weighted image
 Tumor septations, which usually enhance minimally to moderately

Angiography

Hypervascular or moderately vascular masses
 Dilated feeding arteries
 Arterial displacement, no encasement
 Neovascularity
 Occasional arteriovenous shunting
 Obstruction or compression of the splenic or superior mesenteric veins in 50%

MUCINOUS CYSTADENOMA OR CYSTADENOCARCINOMA

Well-demarcated, thick-walled mass 5-33 cm in size (mean, 12 cm)
 Large cysts >2 cm
 Unilocular or multilocular with septa
 Curvilinear mural calcification
 85% occur in pancreatic tail

Ultrasound

Multilocular
 Fixed septa with nodular tumor papillary excrescences
 Complex echo pattern at high gain settings

Computed Tomography

No central stellate septa, no honeycomb appearance
 Mural projections and localized thickening of cyst walls
 Central calcifications

MR Imaging

Round or irregularly oval tumors
 Cystic compartments vary in signal intensity on T1-weighted and T2-weighted images
 Shaggy, papillary excrescences

MRA, CTA, and Conventional Angiography

Hypovascular tumors
 Arterial dilation and neovascularity less frequent
 Arterial encasement or obstruction

Gross and Microscopic Anatomy

The spleen is a reticuloendothelial lymphoid organ located in the left upper abdomen, posterolateral to the stomach, tail of the pancreas, and colic flexure. The adult spleen is 10 to 12 cm in length and weighs an average of 168 g in the adult man and 135 g in the adult woman. Splenic weight positively correlates to height, body weight, body mass index, and body surface area.¹ The spleen is most commonly located between the 9th and 12th ribs with its long axis in line with the 11th rib.²

The visceral peritoneum is reflected at its hilum to form two “pedicles”; one is reflected over the gastrosplenic ligament, and the other is reflected posteriorly over the tail of the pancreas and lienorenal ligament³ (Fig. 102-1). The tail of the pancreas lies within the lienorenal ligament together with the splenic vessels, lymphatics, and nerves and extends to the splenic hilum.

The superior convex surface of the spleen abuts the concavity of the diaphragm and is closely related to the posterior costophrenic recess and the left lung base. The posterior aspect of the spleen lies adjacent to the left adrenal gland or left kidney, and in up to one third of normal cases, part of the spleen is retrorenal.⁴ The anterior surface is related to the splenic flexure of the colon and connected to it by the splenocolic ligament. The splenophrenic, splenorenal, and gastrosplenic ligaments also fix the spleen in its position. The visceral or concave surface of the spleen is related to the stomach and tail of the pancreas in addition to the left kidney and the colon. The splenic hilum occupies approximately 25% to 33% of the splenic surface area.

The splenic artery, a branch of the celiac axis, runs a transverse and often tortuous course along the upper border of the pancreas to reach the splenic hilum, where it divides into five or more major branches.⁵ The splenic vein is formed at the splenic hilum and runs in the lienorenal ligament anterior to the left kidney, the left diaphragmatic crus, and the aorta in a groove along the dorsal aspect of the pancreas (Fig. 102-2). It

joins the inferior mesenteric vein and then the superior mesenteric vein behind the head of the pancreas to form the portal vein. The spleen provides 40% of the blood volume of the portal circulation. The lymphatic vessels are subcapsular and are formed by the drainage of large trabecular tributaries. These vessels drain into the pancreaticocolic nodes at the splenic hilum.

The framework of the spleen consists of collagenous fibrous and elastic tissue forming the capsule (which is less than 1.5 mm thick), trabeculae, and reticular fibers (Fig. 102-3). Blood enters the trabeculae through splenic arterial branches and exits through central arteries (in the white pulp) that are surrounded by the periarteriolar lymphoid sheaths, whose enlargements at irregular intervals are known as malpighian bodies.⁶

The lymphatic sheaths and follicles make up the white pulp of the spleen. The blood vessels transport blood to the sinusoids in the red pulp. Capillaries may open directly into sinusoids or may first pass through spaces in the red pulp. The red pulp performs the phagocytic function of the spleen.

The spleen has between two and five arterial segments, with the avascular plane running parallel to the short axis of the spleen. There are typically two polar arteries and variable segmental arteries supplying the interpolar portion.⁷

The splenic nerve supply is derived from the celiac plexus. It is located along the splenic artery and sends postganglionic sympathetic fibers that innervate the splenic white pulp. These fibers distribute with the vascular and trabecular systems and associate mainly with the central artery and its branches, the periarteriolar lymphatic sheath, the marginal sinus, and the parafollicular zone, with occasional fibers in the follicles.⁸

Physiology

About 4% of the cardiac output or 150 mL of blood per minute flows through the spleen. This amounts to 350 L of blood per day.⁹ The normal transit time of blood in the spleen is 20 to 25 seconds.

The spleen discriminates between normal and abnormal cells and selectively sequesters abnormal and aged red or white blood cells and platelets. The microcirculation of the spleen is thought to direct 10% of splenic arterial blood directly into the venous sinuses and 90% through the red pulp, whose endothelial pores and macrophages remove abnormal particles. Abnormal red blood cells, viruses, bacteria, nuclear remnants (Howell-Jolly bodies), and parasites are removed, with normal erythrocytes left intact. It is not certain what factors sensitize an aged blood cell to splenic destruction; however, it has been suggested that aging erythrocytes have stiffened membranes, which slows or halts their passage through the narrow network of splenic cords, making them an easy target for phagocytosis.¹⁰ About 30% of platelets are normally sequestered within the

Figure 102-1 Anatomic relationships of the spleen. **A.** Splenic ligaments. The spleen has two pedicles: the gastrosplenic and the splenorenal ligaments. **B.** Splenic vessels within the two pedicles. The diagram depicts the ligaments of the spleen and their relationship to splenic vessels. **C.** Anatomic relationships of the splenic hilum to other abdominal organs. (**A** from Dachman AH: *The spleen: Normal anatomy and radiology*. In Friedman AC [ed]: *Radiology of the Liver, Biliary Tract, Pancreas and Spleen*. Baltimore, Williams & Wilkins, 1987, pp 899-910. **B** from Linder HH: *Clinical Anatomy*. East Norwalk, Ct, Appleton & Lange, 1989, p 438. **C** from Meyers MA: *Dynamic Radiology of the Abdomen*. New York, Springer-Verlag, 1988, p 42.)

spleen. When splenomegaly is present, up to 80% of platelets may be sequestered.

The role of the spleen in the immune response is incompletely understood, but it is important in the initiation of humoral and cellular immune responses. The lymphatic tissue in the spleen is unique in that the white pulp of the spleen is perfused by blood rather than by lymph. Thus, it is able to respond rapidly to antigens introduced into the bloodstream.

Figure 102-2 Contrast-enhanced CT shows the course of the splenic vein (arrow) posterior to the pancreas and anterior to the left kidney.

Figure 102-3 Normal trabecular anatomy of the spleen.

The spleen produces a tetrapeptide known as tuftsin that coats leukocytes and facilitates phagocytosis. The absence of tuftsin in splenectomized patients may contribute to the increased incidence of infection reported in these patients by impairing opsonization of bacteria. The spleen is the main site of immunoglobulin M antibody synthesis. Serum immunoglobulin M levels have been shown to decrease significantly after splenectomy.¹¹

Whereas the storage function is not considered to be well developed in the human spleen, it can on average contain 200 to 250 mL of blood and can maintain red blood cell volume in the face of bleeding unless the blood loss is marked.¹² Red blood cells are released into the circulation by splenic contraction, which is controlled by the actions of postganglionic fibers on the capsule and trabeculae. Platelets and white blood cells are also stored within the spleen. In splenomegaly (increased storage), pancytopenia can occur; in asplenia (no storage), one may see pantoctocytopenia.

Radiologic Anatomy and Technique

Splenic size and morphology can be assessed by physical examination or imaging studies. Palpation and percussion of the spleen can be complementary to imaging but are insensitive.¹³ Individuals with a large body habitus and up to 10% of normal children do have palpable spleens. Thus, there is an important role for radiographic imaging in diagnosis of suspected splenic disease.

PLAIN FILM RADIOGRAPHY

The spleen (Fig. 102-4) is often partially outlined on plain films by fat in the greater omentum and distal transverse mesocolon and by the adjacent air-filled stomach or colon.¹⁴ The ventral surface of the spleen may be outlined by fat on lateral views of the chest or abdomen, particularly if the spleen is enlarged. The normal spleen can be visualized in fewer than 100 of 500 (20%) plain films, and the splenic tip can be seen in about 44% of cases.¹⁵ The long axis of the spleen usually parallels the posterior

Figure 102-4 Abdominal radiograph shows spleen outlined by transverse colon (arrows).

ribs and generally does not project significantly below the costal margin.¹⁴ Plain film radiography is useful for detection of moderate or massive splenomegaly and splenic calcifications as commonly seen in granulomatous disease (tuberculosis, histoplasmosis, brucellosis). Curvilinear calcifications may be seen with chronic hematoma, healed abscess, and cysts. Thorotrast deposition, although of historical interest only, is also usually visible on plain films as a fine reticular pattern.

NUCLEAR SCINTIGRAPHY

Splenic scintigraphic evaluation is commonly performed with technetium Tc 99m sulfur colloid (Fig. 102-5). Indications include detection of congenital abnormalities of the spleen and assessment of splenic size, accessory or residual splenic tissue, heterotopic splenic tissue, splenic atrophy, and asplenic states. Splenic lesions larger than 1 cm may be evaluated with planar imaging, but smaller lesions require single photon emission computed tomography (SPECT) or SPECT/CT.¹⁶

POSITRON EMISSION TOMOGRAPHY

Fluorine-18 fluorodeoxyglucose (¹⁸F-FDG) positron emission tomography/computed tomography (PET/CT) is established as a powerful imaging tool for cancer detection and monitoring of response to therapy. There is faint radiotracer uptake in normal splenic tissue (Fig. 102-6). Diffuse increased splenic uptake can be present with the use of marrow-stimulating factors and hematopoietic disorders, as the spleen is a site of extramedullary hematopoiesis.¹⁷ Focal or diffuse pathologic increased ¹⁸F-FDG uptake is present in malignant neoplasms that involve the spleen.¹⁸

ANGIOGRAPHY

The splenic artery is approximately 13 cm in length (range, 8-32 cm). Trifurcation of the celiac trunk into the hepatic, splenic, and left gastric arteries is considered conventional and can be found in 85% of humans.¹⁹ The splenic artery usually originates just distal to the left gastric artery.^{14,20} In 15% of cases, all three branches of the celiac trunk arise at the same point.²¹ Normal variations include origin of the splenic artery from the ventral or right surface of the celiac axis and origin from the aorta or superior mesenteric artery.²⁰ A branch supplying

Figure 102-5 ^{99m}Tc-sulfur colloid scan. **A.** Anteroposterior projection planar image shows normal splenic activity in the left upper abdomen. **B.** SPECT image shows greater activity in the spleen compared with the liver.

Figure 102-6 Normal PET/CT scan. **A.** Normal coronal view CT image. **B.** Normal coronal view PET image. **C.** Normal fused PET/CT image. The spleen shows normal activity (arrows).

the upper splenic pole may originate separately from the celiac axis, giving the appearance of a double splenic artery.²² The splenic artery can be divided into suprapancreatic, pancreatic, prepancreatic, and perihilar segments.⁵ Its tortuosity is variable and increases with age. The most tortuous segment is usually the pancreatic segment, which runs along the dorsal surface of the pancreas and gives off small pancreatic branches. The pancreatic tail and the perihilar segment run between the spleen and the tail of the pancreas.

There are two basic splenic shapes based on arterial configuration: the distributed type and the compact type. The distributed configuration (70% of cases) consists of a short splenic artery with numerous small branches that penetrate the splenic hilum in a distributed fashion. The compact configuration (30% of cases) has a narrow hilum in which the arterial branches are few and large.²³

The splenic artery also supplies portions of the pancreatic body and tail. The dorsal pancreatic artery arises from the first 1 to 3 cm (suprapancreatic segment) of the splenic artery and the greater pancreatic artery (arteria pancreatica magna), which arises from the middle segment of the splenic artery and supplies the tail of the pancreas.²⁴ Another branch, the artery of Buhler, may course inferiorly to communicate with the superior mesenteric artery.²² The short gastric arteries and the left gastropiploic artery usually arise just proximal to the first division of the splenic artery.²⁰

In the parenchymal phase of splenic arteriography, splenic density is dependent on the ratio of splenic volume to the volume of contrast material injected. It is often homogeneous or slightly speckled. Venous anatomy is normally visualized about 7 seconds after arterial injection. Splenic venous anatomy can also be demonstrated with splenoportography.

ULTRASOUND

Ultrasound can be useful in evaluating the spleen, which is best scanned in the left anterior oblique, right lateral decubitus, or prone position. Ultrasound evaluation is best performed with a curved array transducer with a median frequency of 3 to 5 MHz. Use of a subcostal or oblique intercostal plane can

increase the sonographic window. An anterior approach is often limited by gastric or colonic gas. Transverse and longitudinal (coronal) imaging should be obtained (Fig. 102-7). Full or varying degrees of inspiration will improve visualization of the paradiaphragmatic portion of the spleen, which is the most difficult to image. It is often helpful to fill the stomach with fluid for scanning in the supine position. The transducer may be moved in an arc along the intercostal space or in a sector motion. A convex transducer may improve visualization of the “blind areas” adjacent to the dome of the diaphragm.²² Care should be taken in differentiating a prominent lateral segment of the left lobe of the liver, which may wrap around the spleen. When there is a paucity of intra-abdominal fat in thin patients, as in children and young women, the lateral segment of the left lobe may give the appearance of a pseudoperisplenic lesion.²⁵ This can simulate a fluid collection superior and lateral to the spleen.²⁵

Normal splenic parenchyma has a homogeneous, mid- to low-level fine tissue echotexture punctuated by occasional bright echoes representing blood vessels. The spleen is slightly more echogenic than normal liver and markedly more echogenic than normal renal parenchyma.²⁶ However, if the liver echogenicity is abnormal, optimization of the time gain control curve and detection of texture abnormalities of the spleen may prove difficult. The size and shape of the spleen and position of the hilum and its relationship to the diaphragm, stomach, pancreas, and left kidney should be identified.

There are multiple methods for splenic size measurement. The spleen is roughly $12 \times 7 \times 4$ cm in an adult, corresponding to a 150-g spleen. In clinical practice, we use 12 to 13 cm as the maximal length of the spleen as seen in the right lateral decubitus position, measured from upper to lower pole.²⁷ Size criteria have also been established for children by this method.²⁸ Estimations of splenic volume have been described by use of a splenic volumetric index with both ultrasound and CT.²⁹ This is the product of the maximal length, width, and anterior-posterior thickness of the spleen divided by 27, with a normal range of 8 to 34.^{27,28} Another method is to multiply the transverse and vertical dimensions of the spleen taken from an image in which the spleen has maximal cross-sectional size.^{27,28}

Figure 102-7 Spleen: sonographic features.

A. Longitudinal scan shows a borderline-sized spleen with a splenule (arrows) in the splenic hilum. **B.** Color Doppler shows the intrasplenic arteries (red) and veins (blue). **C.** Power Doppler strikingly shows the vascularity of normal splenic parenchyma.

Ultrasound is useful in detecting and characterizing focal lesions and in estimating splenic size and volume. Color Doppler ultrasound is helpful in interrogating the splenic artery and vein. This can be useful in differentiating vascular structures, such as normal vessels or aneurysms, from non-vascular structures, such as pancreatic pseudocysts.³⁰ Power Doppler may help show blood flow in the spleen, particularly in assessing decreased flow (as in sickle cell crisis or infarction). Splenic elasticity measured with real-time tissue elastography, which measures the parenchymal stiffness, can be used as a marker of portal hypertension in patients with chronic liver disease.³¹

Ultrasound microbubble contrast agents, which have been used to characterize liver lesions, can characterize splenic lesions and improve visualization of splenic infarctions and lacerations.^{32,33}

COMPUTED TOMOGRAPHY

CT superbly demonstrates the size, shape, location, and texture of the normal spleen as well as intrasplenic abnormalities. Technical artifacts may result from motion, beam hardening, or dynamic scanning. The relationship of the spleen to the pancreatic tail, left lobe of the liver, diaphragm, left adrenal gland, left kidney, stomach, splenic flexure, and adjacent mesenteric and omental fat is reliably depicted by CT. The posterior surface of the spleen abutting the left hemidiaphragm is called the bare area and has a constant relation to Gerota's fascia.³⁴ This portion of the spleen is about 2 to 3 cm long and may be outlined by air in the posterior costophrenic

sulcus. The point of reflection of the splenorenal ligament at the bare area is thought to correspond to the intermediate ridge of the spleen.³⁴ The bare area is useful in differentiating ascites from pleural effusion because ascites is excluded from the bare area.³⁴

CT displays variations in the size, shape, and position of the spleen³⁵ (Fig. 102-8). Ventral and caudal shift of both the liver and the spleen is seen when the patient turns from the supine to the prone position.³⁶ This positional change can be significant if CT is used to plan radiation therapy portals. On non-contrast CT, the spleen is homogeneous in attenuation and measures 5 to 10 Hounsfield units (HU) less than a normal liver, between 40 and 60 HU.^{30,37-39} Unenhanced scans are useful for the detection of splenic calcifications, such as those seen in abscesses, granulomas, hematomas, parasitic cysts, congenital cysts, and infarctions.⁴⁰ The omental and mesenteric fat surrounding the spleen sharply demarcates the capsule and hilar vasculature even without contrast enhancement. The splenic artery is often tortuous and may appear curvilinear, round, or oval on axial CT scans. The splenic vein may vary in its relationship with the pancreas, and the peripancreatic fat can mimic a dilated pancreatic duct.⁴¹

The splenic index, described with ultrasound, has also been applied with CT. A simplified CT splenic index uses the product of the maximal length (L), width (W), and anterior-posterior thickness (T) of the spleen, with a normal less than 480. A volume can be calculated from the splenic index $V = 30 \times 0.58 \times L \times W \times T$.⁴² Semiautomated and fully automated methods of detection of splenic volume can be performed by either manual or automated segmentation of the spleen. Studies in children

Figure 102-8 Variations of splenic morphology on CT. On axial images, the spleen may have several normal configurations because of prominent lobulation or ridging. K, kidney; St, stomach. (From Piekarski J, Federle MP, Moss AA, London SS: *Computed tomography of the spleen*. Radiology 135:683–689, 1980.)

Figure 102-9 Normal pattern of splenic enhancement on multidetector CT. **A.** Arterial phase shows a mottled enhancement pattern due to differential flow of contrast material in the red and white pulp of the spleen. **B.** Portal venous phase shows uniform splenic enhancement.

have shown that the ratio of splenic volume to the body weight decreases exponentially with age from 4.5 cm³/kg at 1 month to 2.4 cm³/kg at 25 years of age.⁴²

Contrast enhancement is generally indicated for the diagnosis of splenic disease and in distinguishing splenic from pancreatic or adrenal abnormalities. Bolus injection of intravenous iodinated contrast material produces dense enhancement of the hilar vasculature and an initial heterogeneous blush, sometimes with striped or mottled patterns (“zebra spleen”)⁴³ (Fig. 102-9). Slow infusion of the contrast agent creates a uniform increase in parenchymal density.^{36,43} This is due to variable rates of flow through the red pulp.^{43,44} A homogeneous splenic blush should be seen within 2 minutes after bolus injection.³⁵ A detailed analysis of the patterns of inhomogeneity after bolus injection suggests that a mottled pattern is due to uneven enhancement in the capillary phase, and curvilinear low densities correspond to intrasplenic veins.⁴⁵ Splenic inhomogeneities lasting longer than 40 seconds after peak aortic enhancement indicate a pathologic process, whereas those lasting less than 40 seconds represent normal, hemodynamically related inhomogeneities.^{45,46}

Splenic perfusion can be calculated with dynamic CT by drawing regions of interest on the spleen and aorta and calculating time-attenuation curves. This technique has been

used to study splenic perfusion in correlation with portal pressures. Splenic arterial perfusion is lower in patients with chronic liver disease (0.92 mL/min) compared with normal controls (1.35 mL/min).⁴⁷ This is similar to values of 0.96 to 1.19 mL/min/g based on rare gas inhalation washout studies.⁴⁸

Splenic parenchyma enhances significantly higher during the arterial phase with 400 mg/mL iodine-containing contrast agents compared with 300 mg/mL, but parenchymal enhancement is similar during the portal venous phase. As portal venous imaging is typically used to assess splenic parenchyma, intravenous contrast agents with a higher concentration of iodine do not improve CT imaging. However, visualization of the splenic artery and its branches may be better achieved with a higher concentration of contrast agent during the arterial perfusion phase.⁴⁹

MAGNETIC RESONANCE IMAGING

New magnetic resonance imaging (MRI) techniques have increased the role of MRI in detection and characterization of splenic diseases. MRI is an excellent tool for the evaluation of focal and diffuse pathologic processes of the spleen. Rapid scanning techniques allowing breath-hold imaging and respiratory

Figure 102-10 Normal spleen: MRI features.

A. Axial T1-weighted image shows that the spleen is hypointense to liver. **B.** Axial T2-weighted image shows that the spleen is hyperintense to liver. **C.** Axial contrast-enhanced T1-weighted fast spoiled gradient recalled image shows the mottled arterial enhancement of splenic parenchyma.

gated techniques have reduced the motion artifacts related to the spleen's proximity to the diaphragm and artifacts due to bowel motion.⁵⁰⁻⁵⁵

The large fractional heme content in the spleen results in long T1 and T2 relaxation times compared with the liver. Thus, on T1-weighted images, the normal MR signal intensity of the spleen is less than that of the liver but slightly greater than that of muscle. On T2-weighted images, the spleen has higher signal intensity relative to liver (Fig. 102-10).^{56,57} The inherent increased T2 signal can result in poor contrast between normal and abnormal spleen.^{50,53,58} In infants, the spleen signal intensity differs from that of children or adults. The T2-weighted signal intensity gradually increases from isointense to hypointense relative to the liver during the first week of life to moderately hyperintense to the liver by 8 months of age.⁵⁴ This may be due

to the relatively large amount of red pulp at birth. The non-thrombosed blood is dark on T2-weighted images. It is important not to mistake this signal characteristic for disease in the neonate.⁵⁴

Imaging of the spleen includes precontrast and postcontrast fast T1-weighted fat-suppressed gradient-echo images for improved lesion detection and characterization. With intravenous gadolinium contrast enhancement, the spleen demonstrates an early striped or arcuate pattern that becomes homogeneous approximately 60 to 90 seconds after the administration of contrast material.^{52,56} Iron deposition or iron-containing lesions in the spleen can be detected from their reduced signal intensity on in-phase T1-weighted (long echo time) gradient recalled echo images compared with that on opposed-phase images (short echo time).^{59,60}

Alcohol Ablation

Radiofrequency Ablation

Splenic Arterial Interventions

Embolization in Splenic Trauma

Embolization in Hypersplenism

Embolization in Portal Hypertension

Embolization of Splenic Artery Aneurysms or Pseudoaneurysms

Embolization in Splenic Arterial Steal Syndrome

Complications of Splenic Arterial Embolization

Transarterial Splenic Irradiation

Interventions in the spleen have not been performed widely because of the perceived increased risk of complications, especially bleeding. A widely prevailing notion is that splenic interventions result in increased morbidity from hemorrhagic complications. This perception partly stems from the fact that splenic interventions are performed infrequently compared with interventions in other abdominal viscera, and if a more accessible lesion is present in another organ, most operators prefer to sample the other lesion rather than the splenic lesion. However, with increased familiarity with these procedures and availability of finer needles, we are now able to perform these procedures more safely and confidently.

The literature reveals that the rates of complications are much lower than anticipated. In fact, mortality is much more common from liver and pancreatic interventional procedures than from splenic interventions, probably because of the higher number of liver and pancreatic procedures performed. The success rate is 91% for splenic biopsy, 100% for splenic fluid aspiration, and 86% for splenic fluid drainage.¹ These high success rates have been the prime impetus for widespread acceptance of splenic interventions in clinical practice.

This chapter covers the entire spectrum of splenic interventions with focus on image-guided biopsy, catheter drainage, alcohol ablation of cysts, radiofrequency ablation (RFA), and splenic artery embolization.

General Preparation of the Patient

Splenic interventions need no special prerequisite or preparation, and the general guidelines for interventions in the other

abdominal viscera apply. However, a more meticulous attention may be given to the clotting and coagulation parameters, and the following laboratory values are generally recommended: platelet count higher than 50,000/ μ L; international normalized ratio below 1.2; and activated partial thromboplastin time, 20 to 33 seconds.

The patients are instructed to fast either overnight or for 8 hours, as applicable. The procedures are usually performed under conscious sedation with midazolam or fentanyl for adults. Typically, 1% lidocaine local anesthetic is injected in the skin and abdominal wall. However, pediatric patients may require general anesthesia with dedicated support by the pediatric anesthetic team. Securing an intravenous access before the procedure is considered mandatory.

The patients are monitored for 3 hours after the percutaneous procedure. Regular monitoring of blood pressure and pulse rate is advisable. We monitor the vital signs every 15 minutes for the first hour and every 30 minutes for the next 2 hours. Patients who remain stable in the observation period with no or only minimal discomfort can be discharged home. The patients are instructed to avoid significant physical exertion and lifting of heavy weights for at least 3 days.

Image-Guided Biopsy

The central theme of biopsy is to obtain tissue diagnosis by minimally invasive means to preclude the need for unnecessary splenectomy. Thus, the prime candidates for biopsy are patients with an indeterminate solid or cystic lesion in whom a definitive diagnosis cannot be established after clinicoradiologic correlation. The most common clinical scenarios requiring biopsy of a focal splenic lesion include patients with a known extrasplenic neoplasm and patients with known or suspected lymphoma.

Depending on the lesion, either computed tomography (CT) or ultrasound (US) guidance can be used. The choice also depends on the comfort level of the radiologist and the visibility of the lesions by either modality. In general, US is the preferred modality because of real-time guidance and quicker access. Moreover, Doppler US can also be performed before and during the biopsy to detect and to avoid large hilar vessels.

General aseptic and guiding principles apply for image-guided biopsy procedures. The biopsy sample is taken in suspended respiration. The most peripheral lesions are preferably sampled to allow a shorter parenchymal needle track and to avoid inadvertent injury to the hilar vasculature. Biopsy is done from the periphery of the lesion to decrease the possibility of obtaining necrotic material from the center. Lesions near the dome of the diaphragm need real-time US guidance or gantry tilt CT technique to avoid puncture of the pleura. US or CT is usually performed at the end of the procedure to rule out hematoma formation.

Figure 103-1 US-guided biopsy of focal splenic mass. **A.** A focal, heterogeneously echogenic lesion is seen in the spleen on US measured between the calipers labelled A. **B.** The focal lesion is seen with needle in situ (arrow). The histopathologic evaluation revealed hamartoma.

Figure 103-2 CT-guided biopsy of splenic mass. **A.** Axial CT shows a 17-gauge coaxial needle in the splenic parenchyma. **B.** Postprocedural CT shows the biopsy track (arrow). The histopathologic diagnosis was extramedullary hematopoiesis.

One of the more controversial areas in splenic lesion biopsy is the size of the needle used. In general, the sizes range from 18- to 22-gauge for core biopsy and 20- to 23-gauge for fine-needle aspiration (Figs. 103-1 and 103-2). Core needle biopsy has an approximately 88% or better sensitivity in making a diagnosis in varying studies in the literature.¹⁻¹² The success rates, however, are lower with fine-needle aspiration procedures.^{2,5} A spinal needle is used for lesions less than 8 cm in depth, and a Chiba needle is used for lesions situated deeper than 8 cm.

The number of passes obtained is usually at the discretion of the interventional radiologist performing the procedure. Additional passes are obtained in cases of suspected lymphoma to obtain material for immunophenotyping by flow cytometry and cell block. If cytology shows no evidence of malignant transformation, a portion of the aspirate is sent for culture and sensitivity profiling.

The complications that may be encountered include hemorrhage, pneumothorax, pleural effusion, and bowel injury (Table 103-1 and Fig. 103-3). The most dreaded of the complications is uncontrolled non-self-limited hemorrhage, which may require blood transfusion, embolization, or splenectomy. One method to ensure hemostasis along the needle track is to inject gelatin sponge at the end of the procedure. However, if hemorrhage does occur nevertheless, it is then managed with aggressive fluid resuscitation and blood transfusions. Progressive hematomas not responding to conservative management may

TABLE 103-1 Complications of Splenic Biopsy			
Study	Needle (gauge)	Patients	Complications
Tam et al, ¹² 2008	22	147	1.9% major (two splenectomies) 14.7% minor 2%
Liang et al, ⁷ 2007	21, 18	46	None
Kang et al, ⁶ 2007	22	78	None
Muraca et al, ⁴ 2001	18-21	30	None
Keogan et al, ³ 1999	20-22	18	None
Lieberman et al, ² 2003	20-22	20	10% minor (hemorrhage)
Lucey et al, ¹ 2002	18-23	24	10% (two splenectomies and one case of bleeding)

be subjected to catheter angiography with embolization. Splenectomy may be resorted to if all else fails.

In general, these complications occur with increasing frequency with increasing caliber of the biopsy needle. Fine-needle aspiration is generally considered safer than core biopsy. In one series, no complications were reported in 1000 blind

Figure 103-3 Postbiopsy complications. **A.** Postbiopsy CT showed a left-sided pneumothorax that was successfully managed with catheter drainage (arrow). **B.** Postbiopsy CT shows hemorrhage (arrow) in the left upper quadrant, which was conservatively managed.

Figure 103-4 Catheter drainage of splenic abscess. **A.** Noncontrast CT demonstrates a focal fluid-density hypodense lesion in the splenic parenchyma. **B.** US revealed that the focal lesion was predominantly anechoic with dependent debris, suggesting an abscess. The echogenic needle tip is seen (arrow) within the abscess cavity. **C.** Follow-up CT after the procedure shows the pigtail catheter in the lower pole of the spleen with collapse of the abscess cavity.

fine-needle aspiration procedures done with 22-gauge needles, whereas another series reported a complication rate of 12% (four of 32 patients) with a 14-gauge core biopsy needle, with one patient needing splenectomy and three needing transfusions^{8,9} (Table 103-1).

Catheter Drainage

Traditionally, splenic abscesses were managed with antibiotics, and splenectomy was resorted to if antibiotic treatment failed. Image-guided aspiration with catheter drainage is an excellent minimally invasive alternative with a high success rate.^{1,13-15} In addition to being less invasive than surgery, it also helps preserve the spleen and avoid the long-term immunologic dysfunctions seen with splenectomy.

The ideal collection amenable to drainage is a unilocular collection with a discrete wall without internal septations or loculations. As with biopsy, collections in the periphery, especially in the middle or lower pole, are easier to drain. A trial aspiration is done, and the catheter is inserted if frank pus is aspirated. The most commonly used catheters are the pigtail catheters in varying sizes ranging from 7F to 12F (Fig. 103-4).^{1,13} In general, more viscous abscesses need larger bore catheters, and the catheter may need to be upgraded to a larger one in case of inadequate drainage.

Although multiloculated abscesses are more difficult to drain, drainage of these abscesses can be done with one or more catheters. The hydrostatic pressure that is created by the drainage can break the septations and drain the entire cavity. The septations can also be broken by injection of urokinase through the catheter.¹⁶

As with biopsy, either US or CT may be used for guidance and navigation. The two commonly used methods are the trocar technique and the Seldinger technique. Whereas the trocar technique is quicker, the Seldinger technique is more precise at the expense of a slightly longer procedure time. There is also a possibility of loss of access in cases of buckling or kinking of the guidewire in the Seldinger technique.

It is mandatory to flush catheters with saline every 8 hours to prevent clogging of the lumen and the side holes. Repeated flushing also makes the collection less viscous and easy to drain. The catheter can be removed when the tube drains less than 10 mL/day for 3 consecutive days. Care should be taken to straighten the hook-shaped curve of the pigtail catheter before pulling it out to minimize pain as well as soft tissue injury.

The drainage catheter is often placed for about 7 to 14 days. The prerequisites for catheter removal are patient improvement clinically (including normal temperature and white blood cell count) and resolution of the cavity. Typically, the catheter is

discontinued when the catheter output is 10 mL/24 hours and no residual cavity is seen on imaging.

Again, as with image-guided biopsy, hemorrhage is a serious complication, and the rate of significant uncontrolled bleeding requiring splenectomy is considerably higher compared with biopsy.^{1,14} Hence, meticulous monitoring for a longer period (24 hours) is advisable versus the shorter (3 hours) monitoring time after biopsies.

Alcohol Ablation

Alcohol ablation sclerotherapy works on the principle of denaturation of proteins in the wall of the cyst, eventually leading to cell death and fibrosis of the cyst wall. It has been extensively used in symptomatic cysts and hydatid cysts in the solid viscera, especially in hepatic and renal cysts.¹⁷⁻¹⁹ Other sclerosants, like tetracycline, have also been used successfully in children.²⁰ The advantages of this therapy are its easy availability, high efficacy, and technical ease compared with surgery.

The symptomatic splenic cysts may be treated by alcohol ablation. These cysts are usually large, and therefore an 8F to 10F pigtail catheter is placed inside the cyst under image guidance (Fig. 103-5). All the fluid is aspirated, which is then sent for cytologic and microbiologic analysis. Contrast material may be injected through the placed pigtail catheter at this point to ensure optimal catheter placement and to rule out any intraperitoneal spillage. An intraperitoneal spillage of contrast material would be a contraindication to alcohol therapy.

Once catheter access has been achieved and the fluid content aspirated, 95% ethyl alcohol is injected into the cyst. The volume injected is generally half the amount of fluid that was aspirated (up to a maximum of 100 mL). After 20 minutes, the entire injected alcohol is reaspirated, and this is confirmed on CT. A follow-up CT scan after 3 months is obtained to look for any recurrences. The ablation therapy may be repeated in case of recurrence.

The complications include pain, bleeding, hypotension, infection, and damage to adjacent structures due to inadvertent spillage of the sclerosant.

Radiofrequency Ablation

RFA is based on the principle of radiofrequency deposition at the needle tip, which leads to ionic agitation and frictional

heating. At temperatures in excess of 50°C, tissue desiccation and protein denaturation result in coagulative necrosis.

RFA has been used for local treatment of splenic neoplasm, especially secondary metastases. Significant shrinkage of the lesion has been demonstrated at 6-month follow-up.²¹ Improvement in platelet count as well as liver function has been documented after ablation of 30% to 40% of splenic volume in patients with hypersplenism.²²⁻²⁴ RFA has also been used to desiccate the splenic tissue surrounding an infected hydatid cyst before surgical removal.²⁵

Although RFA has been successfully used in a variety of body parts for a variety of indications, the literature on splenic RFA is relatively sparse, again likely attributable to the fear associated with bleeding complications in splenic interventions. However, counterintuitively, RFA has been used to treat grade 4 splenic lacerations in pigs.²⁶ Further studies are required before RFA becomes a mainstream interventional tool in managing splenic lesions.

Splenic Arterial Interventions

Arterial interventions in the spleen are increasingly used nowadays and may be substituted for surgery in specific clinical indications. A good knowledge of arterial anatomy is needed for successful embolization as well as prevention of unintended complications.

EMBOLIZATION IN SPLENIC TRAUMA

The spleen is the most commonly injured solid abdominal organ. Because of the risk of fatal sepsis after splenectomy and impaired immunity to organisms, there has been a paradigm shift from surgical to nonsurgical management. This conservative management strategy for splenic trauma has a significant inherent failure rate (from 2% to 52%).^{27,28} Splenic arterial embolization may be used to reduce this failure rate and to preclude the need for secondary splenectomies.

Embolization is especially indicated when there is evidence of arterial injury on CT. In such cases, microcoils are deployed as distally as possible in the bleeding artery to preserve the perfusion to the rest of the spleen. Distal splenic embolizations are associated with higher rates of infarction and intrasplenic air.²⁹ Air, in this setting, is not indicative of abscess formation. Proximal embolization is indicated in patients with a high risk

Figure 103-5 Alcohol ablation of splenic cyst. **A.** Contrast enhanced CT shows a large bilobed cyst (arrows) in the spleen that was symptomatic because of the mass effect. **B.** Axial CT shows a drainage catheter placed across the two cysts. The nondependent low-density fluid in the cysts represents the 95% alcohol injected into the cysts for the ablation procedure. **C.** Postablation CT scan shows marked reduction in the size of the cyst (arrow).

Figure 103-6 Splenic artery embolization for splenic laceration. **A.** Selective celiac artery angiogram demonstrates extravasation of contrast material (arrowheads) in a patient with grade 4 splenic laceration. **B.** Postprocedural angiogram performed after placement of twelve 0.035-inch Tornado coils (arrow) in the main splenic artery shows complete occlusion of the splenic artery.

of secondary rupture to decompress the splenic parenchyma and to reduce the pressure in the system (Fig. 103-6). This allows collateralization, principally through the short gastric and gastroepiploic arteries, to the patent distal splenic, transgastric, and transpancreatic arteries, and the relative hypotension produced allows splenic repair and regeneration without infarction.^{30,31} Also, in patients who have intraprocedural hemodynamic deterioration, a quicker, more proximal embolization can be performed.

EMBOLIZATION IN HYPERSPLENISM

Hypersplenism, seen most commonly in patients with cirrhosis and portal hypertension, is characterized by sequestration as well as destruction of corpuscular elements of blood. Proximal splenic arterial embolization is usually unsuccessful in this setting because of extensive collateral blood flow. Incomplete or partial splenic embolization is advocated in this setting to reduce the amount of viable splenic parenchyma. Ideally, the aim is 60% to 70% splenic parenchymal infarction because the hematologic response correlates with the degree of infarction. The general guideline, usually termed the Spigos technique, is as follows³²:

- Pneumococcal vaccines are administered before the procedure.

- Broad-spectrum antibiotics are administered 8 to 12 hours before the procedure and continued for 2 weeks after the procedure.

- Local antibiotics are suspended in the embolic solution.

- The procedure is performed under strict aseptic precautions.

- Selective catheterization is attained beyond the origin of the major arteries to the pancreas to prevent their embolization.

- Embolization is performed with particulate embolic agents. Avoid excessive embolization (not more than 80% infarction).

- Provide postprocedural pain management and prevent pulmonary complications.

Two methods of embolization include selective partial embolization and nonselective partial embolization. Selective partial embolization involves superselective cannulation and embolization of distal branches of the splenic artery. The rest of the branches are left untreated and provide blood flow to

viable splenic parenchyma. A check angiogram in the parenchymal phase reveals the viable splenic parenchyma with areas of dropout of contrast material that correspond to the degree of infarction.

Nonselective partial embolization involves embolization with the catheter tip in a more proximal position in the main splenic artery, distal to the origin of major pancreatic branches. Generalized reduction of parenchymal blush is the usual endpoint.

Although proximal splenic arterial occlusion is ineffective treatment of hypersplenism, it may be used preoperatively to reduce intraoperative blood loss in patients undergoing splenectomy, especially because most of these patients have thrombocytopenia due to hypersplenism.

EMBOLIZATION IN PORTAL HYPERTENSION

Partial splenic embolization may also have a place in the management of portal hypertension and resistant variceal hemorrhage. Embolization decreases venous return from the spleen, thereby reducing portal pressures.

EMBOLIZATION OF SPLENIC ARTERY ANEURYSMS OR PSEUDOANEURYSMS

Aneurysms of the splenic artery are usually small (<2 cm) and saccular and are commonly located at branch points. They are more commonly found in multiparous women and patients with cirrhosis and portal hypertension. Pseudoaneurysms of the splenic artery most commonly occur as sequelae of pancreatitis. The release of proteolytic enzymes in pancreatitis results in necrotizing arteritis and fragmentation of elastic fibers in the vessel wall with resultant destruction of vessel wall architecture. This results in pseudoaneurysm formation, which may lead to gastrointestinal bleeding.

Splenic artery aneurysms are embolized in cases of symptomatic aneurysms, in women of childbearing age, in portal hypertension, and with size larger than 2.5 cm. It is considered that all splenic artery pseudoaneurysms need treatment regardless of size and symptoms as the natural history of an asymptomatic pseudoaneurysm of the splenic artery is not known. Traditionally, treatment involved surgical ligation. Recently, however, endovascular transcatheter embolization is considered the management of choice.³³⁻³⁵ Coils can be deployed directly

into the aneurysmal sac, or the neck of the aneurysm can be excluded by the "sandwich method" of deploying coils both proximal and distal to the neck. Percutaneous image-guided thrombin injection can also be used in selective cases.³⁶⁻³⁸ Endoscopic US-guided thrombin injection has also been tried.³⁹ A flexible self-expanding covered stent to exclude the aneurysm is an attractive option as it preserves the blood flow through the splenic artery.

EMBOIZATION IN SPLENIC ARTERIAL STEAL SYNDROME

Splenic arterial steal syndrome is a rare complication of liver transplantation, the classic triad being liver failure, reduced hepatic arterial perfusion, and increased blood flow in the splenic circulation after liver transplantation. This is due to decreased splenic arteriolar resistance, which is common in cirrhotics with portal hypertension. Prompt diagnosis and management are essential as it mimics graft failure.⁴⁰

Although hepatic arterial reimplantation into the aorta is the ideal therapeutic option, a minimally invasive procedure is usually preferred because of increased morbidity associated with the second surgery. Splenic arterial embolization is an attractive option to decrease shunting of blood into the splenic circulation.⁴¹

COMPLICATIONS OF SPLENIC ARTERIAL EMBOLIZATION

Potential complications of splenic arterial embolization include hemorrhage, infarction, abscess formation, systemic infection, iatrogenic vascular injury (splenic vein thrombosis), coil migration, necrosis of stomach wall, and pancreatitis. A postembolization syndrome is common; it consists of low-grade fever and left upper quadrant pain with leukocytosis and may require analgesics for relief of symptoms.

Transarterial Splenic Irradiation

External beam radiotherapy has been effective in lymphoma, leukemia, myelofibrosis, idiopathic thrombocytopenic purpura, and polycythemia vera. Intra-arterial irradiation is emerging as an encouraging alternative to decrease complications associated with external beam radiotherapy and to increase the maximum allowable dose. The usual agent is yttrium-90 microspheres.⁴²⁻⁴⁴

A variety of interventional tools and modalities have been used with varying success in management of splenic lesions. Awareness of the indications and limitations of individual techniques is essential to minimize potential complications in splenic interventions.

Splenic-Gonadal Fusion

Heterotaxy Syndromes

Asplenia Syndrome

Polysplenia Syndrome

Embryology

Splenic development begins in the fifth week of gestation from a condensation of mesenchymal cells that aggregate between the two leaves of the dorsal mesogastrium. Aggregates from several adjoining areas fuse to form a lobulated embryonic spleen.¹ Rotation of the stomach and growth of the dorsal mesogastrium cause the translocation of the developing spleen from the midline to the upper left side of the abdominal cavity, and the mesogastrium fuses with the peritoneum over the left kidney, forming the splenorenal ligament (Fig. 104-1).² This causes the lienorenal ligament to fuse dorsally, and the splenic artery has a course to the left behind the peritoneum as it enters the splenorenal ligament in the adult.

The capsule, connective tissue framework, and parenchyma of the spleen form from differentiated mesenchymal cells. The spleen serves a hematopoietic function from the fourth to the eighth month of gestation. Lymphocyte and monocyte production, however, continues throughout life.¹

Splenic Clefts, Lobulations, and Bands

In the fetal period, the spleen is lobulated; however, the lobulations normally disappear before birth. Lobulation may persist along the medial (hilar) aspect of the spleen and is considered a normal feature of splenic anatomy. Notches or clefts along the superior border are remnants of the grooves that originally separated fetal lobules.² An abnormally deep fissure may give the appearance of a band. If the fissure traverses the entire

spleen, a waist is created that may mimic a laceration. Peritoneum may be embedded on this waist and may mimic a hematoma, infarction, or laceration.³ Deep fissures tend to occur along the superior border of the spleen. When they occur along the inferior border, a lobule of splenic tissue may extend medially and anteriorly to the left kidney. Less frequently, the lobule may lie posterior to the upper pole of the left kidney and displace it anteriorly.⁴

Wandering or Ectopic Spleen

Wandering or ectopic spleen refers to migration of the spleen from its normal fixed posterolateral location in the left upper abdomen. The reported incidence is 0.16% on the basis of 3853 splenectomies performed for various indications involving all ages.⁵ It usually is manifested between the ages of 20 and 40 years; 70% to 80% of reported cases are in women in the reproductive age. One third of cases are found in children, most (70%) older than 10 years.⁶

The spleen is normally anchored in the left upper abdomen by two ligaments: the gastrosplenic ligament, which connects the spleen to the greater curvature of the stomach; and the splenorenal ligament, which connects the spleen to the left kidney and the posterior body wall.²

The etiology of wandering spleen may be congenital or acquired. Congenitally, the condition is from absence or weakness of one or more of the ligaments that affix the spleen in its normal position in the upper left abdomen. The spleen is instead solely attached by its vascular pedicle and can become a wholly intraperitoneal hypermobile organ. Rarely, a normal spleen may be seen in the left upper quadrant, and an accessory spleen may be mobile and wander.⁷

The pathologic process also may be acquired as a result of splenomegaly or ligamentous laxity, such as in pregnancy or muscular dystrophies.⁸ There is a higher incidence of wandering spleen in multiparous women, which suggests an etiologic role of hormonal effects and abdominal laxity associated with pregnancy.^{9,10} Wandering spleen has been reported in prune-belly syndrome and in cases of diseases causing splenic enlargement, such as splenic cysts, malaria, Hodgkin's disease, and lymphangioma.¹¹

CLINICAL FINDINGS

The clinical presentation of wandering spleen is variable. Affected patients may be asymptomatic and the condition may be detected incidentally. Diagnosis may be made incidentally as a mass on physical examination or imaging. Classically, a firm, movable, notched mass can be palpated. Symptoms occur when there is pressure on the vascular pedicle of the spleen or when torsion develops.⁸

Figure 104-1 Embryology. **A.** Transverse section at the end of the fifth week shows the spleen developing within the dorsal mesogastrium. **B.** As rotation begins, the splenic artery courses to the left in an area of fusion of the dorsal mesogastrium with the posterior peritoneum. (From Dachman AH: *Normal anatomy and radiology*. In Friedman AC [ed]: *Radiology of the Liver, Biliary Tract, Pancreas, and Spleen*. Baltimore, Williams & Wilkins, 1987, pp 899–915.)

The most common presentation in children is acute abdominal pain. Patients may also present clinically with nonspecific symptoms, such as occasional nausea, emesis, or mild, crampy abdominal pain.¹¹ Pain may be vague in cases of chronic intermittent splenic torsion.¹² Wandering spleen with torsion may involve the tail of the pancreas, resulting in pancreatitis, and the splenic venous occlusion may result in splenomegaly and cause hypersplenism.⁹ Less common presentations of wandering spleen include small bowel or colonic obstruction and even duodenal obstruction due to compression by the splenic pedicle.⁶

RADIOLOGIC FINDINGS

Conventional Radiography

Supine and erect abdominal radiographs may show absence of the normal splenic silhouette or a mobile mass in the left or central abdomen. With the spleen absent from its normal location, bowel loops may fill the splenic fossa.¹³ The left kidney may be elevated and lack the usual splenic impression or hump and may cause elevation of the left hemidiaphragm.¹⁴

With the spleen not fixed in the abdomen, the elongated pedicle of the spleen or the displaced spleen can cause gastric outlet obstruction, small bowel obstruction, or colonic obstruction. Abdominal radiographs can show a distended stomach, a small bowel obstruction pattern, or colonic obstruction. The splenic pedicle may cause a linear defect across the involved bowel segment or colon.^{15–17}

Nuclear Scintigraphy

Technetium Tc 99m sulfur colloid scintigraphy can identify reticuloendothelial activity in the liver as well as in the spleen and is useful in identifying ectopic functional splenic tissue in the abdomen.¹⁸ Similarly, heat-denatured ^{99m}Tc-labeled red blood cell imaging, specific for splenic tissue, provides useful information for spleen size and localization as well as for the specific red blood cell sequestration function of the splenic tissue.¹⁹ A wandering spleen is diagnosed by normal uptake of

Figure 104-2 Wandering spleen. Anterior ^{99m}Tc-sulfur colloid scintigram shows absence of radiotracer activity in the left upper abdomen and uptake in an abnormally located spleen in the pelvis (arrow). The liver also shows normal radiotracer uptake (top). (From Paterson A, Frush DP, Donnelly LF, et al: *A pattern-oriented approach to splenic imaging in infants and children*. *RadioGraphics* 19:1465–1485, 1999.)

radiotracer by functioning splenic tissue in an abnormal location in the abdomen (Fig. 104-2). The lack of tracer activity in a previously demonstrated wandering spleen indicates torsion.²⁰

Ultrasound

Gray-scale sonography and power Doppler sonography are valuable in the diagnosis of wandering spleen and allow the diagnosis of complications such as torsion and infarction.

Figure 104-3 Wandering spleen: sonographic features. **A.** Transverse ultrasound image of the pelvis shows the spleen overlying the bladder. **B.** Color Doppler image shows blood flow in the splenic parenchyma adjacent to the iliac artery.

Sonography can confirm the absence of the spleen in its normal position in the left upper abdomen and can identify the ectopic spleen in the abdomen or pelvis (Fig. 104-3). The ectopic spleen is of uniform echotexture with a peripheral indentation on the mass, representing the hilar vasculature. Use of power Doppler, color Doppler, and duplex sonography allows evaluation of blood flow in the splenic parenchyma and in the major splenic vessels.^{21,22}

Real-time sonography can be used to identify splenic hypermobility and twisting of the vascular pedicle, which can increase risk of infarction. The spleen may be enlarged owing to an intermittent twist of the vascular pedicle and venous congestion.²³

Computed Tomography and Magnetic Resonance Imaging

Contrast-enhanced computed tomography (CT) can diagnose an ectopic spleen and its associated complications and is often performed as patients may present with abdominal pain. A pathognomonic CT finding of a wandering spleen is the absence of the spleen in the upper abdomen and the presence of a well-marginated homogeneously enhancing soft tissue mass in the abdomen or pelvis (Fig. 104-4).²⁴

Features of splenic torsion include poor or absent enhancement of splenic parenchyma, hyperdense pedicle indicating thrombosis, and enhancing splenic capsule from peripheral circulation. The whirl appearance of the splenic vascular pedicle is a specific sign of torsion. Splenomegaly, although not specific, is an important sign of torsion in the setting of a wandering spleen.²⁵ A markedly hypodense spleen due to infarction may be misdiagnosed as a mesenteric cyst, a dilated fluid-filled bowel loop, or an abscess.²⁶ Torsion of a wandering spleen may be associated with intestinal obstruction (due to compression of other abdominal organs), abscess formation, necrosis of the pancreatic tail, and recurrent pancreatitis.²⁷

Magnetic resonance imaging (MRI) has gained popularity in diagnosis of wandering spleen.^{28,29} It can locate the ectopic spleen and identify the viability of the splenic parenchyma as well as depict splenic vessel anatomy.³⁰

Angiography

Although it is not usually required for diagnosis, celiac arteriography may show torsion of wandering spleen by demonstrating a tapered and abruptly twisted distal splenic artery. The

Figure 104-4 Wandering spleen. Coronal contrast-enhanced CT shows abnormally located spleen in the pelvis, with small bowel loops in the left upper abdomen.

venous phase may suggest splenic vein obstruction and may show collateral circulation and varices.³¹ MR angiography can be particularly useful in demonstrating the location and length of the splenic artery before surgery.²⁹

DIAGNOSTIC APPROACH AND THERAPY

When wandering spleen is suspected, radiologic imaging should locate the ectopic spleen and evaluate the anatomy and patency of the splenic vessels. Evaluation of the viability of the splenic parenchyma, including any areas of infarction, is important as it guides therapy.

The definitive therapy for a wandering spleen is surgery. Splenopexy with splenic salvage is the preferred treatment in cases in which the spleen is viable after detorsion and the splenic vein is not thrombosed. Splenectomy is the option in cases of splenic infarction.³²

Accessory Spleen

Accessory spleen is a congenital anomaly caused by failure of embryonic splenic buds to unite within the dorsal mesogastrium and extreme lobulation of the spleen with pinching off of splenic tissue. Its reported incidence ranges from 10% to 30% in autopsy series.^{33,34} Accessory spleen is identified in 11% of patients undergoing contrast-enhanced CT³⁵ and 45% to 65% of patients after splenectomy.³⁶

Accessory splenic tissue measures between 1 and 3 cm in diameter but can be as large as the spleen. It is usually located about the splenic hilum or ligaments.³⁵ The tail of the pancreas is the second most common site for an accessory spleen, accounting for 16% of the cases.³⁴ Accessory spleens can be found in the wall of the stomach, the large bowel, the omentum, the mesentery, and rarely even the scrotum.^{37,38}

The morphologic appearance is identical to that of normal spleen, and the accessory tissue is usually supplied by a branch of the splenic artery and drains into splenic veins. Of the patients with an accessory spleen, 88% were solitary, 8% had two, and 3% had three.³⁵

CLINICAL FINDINGS

Accessory spleen is an incidental finding of no clinical significance in most patients. However, it can become symptomatic because of torsion or spontaneous rupture.³⁹ Accessory spleen is important to identify as it may mimic lymph nodes or tumors, especially in the tail of the pancreas.⁴⁰

Identification of all accessory splenic tissue is important in the setting of idiopathic thrombocytopenic purpura, in which all functional splenic tissue should be removed for the treatment of the hematologic disorder.⁴¹

RADIOLOGIC FINDINGS

Nuclear scintigraphy, sonography, CT, and MRI can identify and characterize accessory splenic tissue. The normal accessory spleen has the same echotexture and enhancement as normal spleen. When the tissue is recognized as an accessory spleen, no further work-up is needed. Diagnostic studies are indicated if this tissue simulates a neoplasm or if therapeutic splenectomy is planned in patients with hematologic disorders.⁴¹

On gray-scale ultrasound, accessory spleen is identified as a round or oval mass about the splenic hilum that is identical to spleen in echotexture. On color or power Doppler ultrasound, a vascular hilum entering the lesion is a diagnostic feature of accessory spleen.⁴² Contrast-enhanced ultrasound has been shown to demonstrate accessory spleen with an enhancement pattern paralleling that of the adjacent spleen.⁴³

On multiphase contrast-enhanced CT, an accessory spleen is usually identified as a well-circumscribed mass about the splenic hilum with an inhomogeneous striped arterial enhancement pattern identical to the spleen (Fig. 104-5).³⁵ Intrapane-creatic accessory spleen can mimic pancreatic neoplasms, such as hypervascular islet cell tumors. The attenuation of the spleen is

Figure 104-5 Accessory spleen: CT findings. An accessory spleen (arrow) is seen with a feeding vessel (arrowhead). It has the same attenuation and enhancement as the main spleen.

typically higher than that of the pancreas on the arterial, pancreatic, and portal venous phases, and similarly, intrapancreatic accessory spleen tends to be higher in attenuation than pancreas on all phases of imaging.⁴⁴ Conversely, hypervascular pancreatic tumors, including islet cell tumor, are hyperattenuating on the arterial phase and isoattenuating or lower attenuating to the adjacent pancreas on the venous phase.⁴⁵

On MRI, accessory spleen is isointense to mildly hypointense to spleen on T1 imaging and isointense to spleen on T2 imaging. Its enhancement pattern is identical to that of spleen on arterial, portal, and late phases of contrast enhancement (Fig. 104-6). Accessory spleen is isointense to spleen on diffusion-weighted imaging. The identical MRI features of accessory spleen to spleen allow the discrimination from pancreatic neoplasms.⁴⁶

^{99m}Tc-labeled heat-damaged red blood cell (^{99m}Tc-HDRBC) scintigraphy is a highly specific method for detection of splenic tissue as up to 90% of the injected HDRBCs are trapped by splenic tissue.⁴⁷ ^{99m}Tc-HDRBC scintigraphy allows selective splenic visualization with an excellent spleen-to-liver ratio; splenic visualization may be impaired when minimal functioning splenic tissue is present, as happens in cases of accessory spleens. In addition, ^{99m}Tc-HDRBC planar imaging scintigraphy and even single photon emission computed tomography (SPECT) offer inferior spatial resolution compared with other cross-sectional imaging modalities. ^{99m}Tc-HDRBC SPECT is frequently used in conjunction with other cross-sectional imaging modalities to diagnose and to precisely localize an accessory spleen (see Fig. 104-6).⁴⁸

Figure 104-6 Intrapancreatic accessory spleen: MRI findings and ^{99m}Tc -HDRBC SPECT. **A.** T1-weighted axial MRI shows an intrapancreatic tail mass (arrow) that is hypointense to pancreas and mildly hypointense to spleen. **B.** T2 fat-saturated MRI shows the intrapancreatic mass (arrow) to be hyperintense to pancreas but isointense to spleen. **C.** Gadolinium-enhanced fat-saturated T1-weighted fast spoiled gradient recalled MRI shows the pancreatic tail mass (arrow) to have arterial enhancement similar to that of spleen. **D.** ^{99m}Tc -HDRBC SPECT shows focal uptake (arrow) near the splenic hilum in the region of the tail of the pancreas.

Splenic-Gonadal Fusion

This rare congenital anomaly is characterized by an abnormal connection between the gonad and the spleen or by ectopic splenic tissue. The left gonad is virtually always involved; only one case of right-sided involvement has been reported.⁴⁹ Before the sixth week of gestation, the splenic anlage developing in the left dorsal mesogastrium is close to the left urogenital fold that contains gonadal mesoderm during rotation of the embryonic gut. The accepted theory is that splenic-gonadal fusion is the abnormal attachment that occurs during the fifth to eighth week of gestation when both organs are close. Splenic-gonadal fusion occurs with a male-to-female ratio of 16:1 and can interfere with the normal descent of the left testis or can cause failure of closure of the processus vaginalis; it is frequently associated with an ipsilateral inguinal hernia and cryptorchidism.⁵⁰

The continuous form, in which the spleen remains attached to the gonad by a fibrous or splenic cord that traverses the peritoneal cavity, is the most common type, occurring in

about 55% of the published cases. Continuous splenic-gonadal fusion is associated with limb defect syndrome and other congenital malformations, including cardiac malformations, thoracic malformations, cleft palate, micrognathia, anal anomalies, spina bifida, craniosynostosis, diaphragmatic hernia, and pulmonary anomalies.⁵¹ The discontinuous form, representing 45% of the cases, is not associated with other congenital anomalies.^{52,53}

The diagnosis of splenic-gonadal fusion should be suspected if there is chronic swelling or mass in the left gonad, especially if there is an associated undescended testis.⁵⁴ The gonadal mass, if palpable, is firm and rubbery and may be poorly delineated from the testis. The first study is ultrasound, which can show a well-defined scrotal mass that is isoechoic to spleen.⁵³ Malignant disease associated with splenic-gonadal fusion is exceedingly rare and occurs in the undescended testis.⁵⁵

^{99m}Tc -sulfur colloid scintigraphy is useful to confirm ectopic splenic tissue and shows uptake in the inguinal or scrotal area.^{56,57}

Heterotaxy Syndromes

ASPLENIA SYNDROME

Situs ambiguus with asplenia, or Ivemark syndrome, is characterized by an absent spleen and duplication of right-sided structures (bilateral right-sidedness), affecting males twice as commonly as females.⁵⁸ Asplenia syndrome occurs in 1 per 10,000 to 1 per 40,000 live births and is due to defects in multiple genes.⁵⁹ It virtually is always accompanied by a variety of congenital malformations, particularly cardiovascular (Figs. 104-7 and 104-8).⁵⁸⁻⁶³ Congenital heart malformations are present in about 85% to 95% of patients with asplenia (Box 104-1). The isolated form of congenital asplenia lacks other developmental anomalies, particularly those of the cardiovascular system.⁶⁴

Abdominal Radiologic Findings

In asplenia syndrome, the aorta and IVC are in juxtaposition on the same side of the spine, which can be identified by sonography or contrast-enhanced CT (Fig. 104-9). The IVC-atrial communication can be evaluated by either modality.⁶⁵ The spleen will be absent, and the liver is symmetric and midline. The splenic artery is absent, and the celiac axis may arise from the superior mesenteric artery. Malrotation of the bowel occurs with the stomach on the right and an abnormal location of the ligament of Treitz, with the jejunal loops of bowel in the right hemiabdomen and the ileal loops of bowel in the left hemiabdomen. This is associated with inversion of the normal

Figure 104-7 Asplenia: gross specimen. Autopsy specimen of a patient with asplenia, infracardiac anomalous pulmonary venous return, atrial septal defect, and pulmonary atresia. The liver straddles the midline. No spleen is identified.

Figure 104-8 Asplenia: associated anomalies. Diagram shows organ positions in situs ambiguus with asplenia. (From Fulcher AS, Turner MA: Abdominal manifestations of situs anomalies in adults. *RadioGraphics* 22:1439–1456, 2002.)

BOX 104-1 DEVELOPMENTAL ANOMALIES WITH ASPLENIA SYNDROME

PULMONARY ANOMALIES

Bilateral trilobed lungs with eparterial bronchi

CONGENITAL HEART MALFORMATIONS

Cardiac malposition

Mesocardia

Dextrocardia

Right-sided aortic arch

Great vessels

Transposition of the great vessels

Pulmonary stenosis or atresia

Venous system

Bilateral superior vena cava

Bilateral inferior vena cava (IVC)

Partial or total anomalous pulmonary venous drainage

Cardiac defects

Hypoplasia or absence of one ventricle

Double-outlet right ventricle

Ventricular septal defect

Atrial septal defect

Absent coronary sinus

Single coronary artery

Figure 104-9 Situs ambiguus with asplenia. **A.** Transverse contrast-enhanced CT scan of the lower chest of a 48-year-old man shows dextrocardia and azygos continuation of the inferior vena cava. The aorta is located to the right of the enlarged azygos vein (arrow). The scan also shows left lower lobe collapse and a left pleural effusion. **B.** CT scan obtained 15 mm caudad to **A** shows the stomach (S) and colon (C) in the expected location of the spleen. The hypoplasia of the anterior segment of the right hepatic lobe allows cephalic migration of the colon. **C.** On another CT scan obtained caudad to **B**, the gallbladder (GB) lies in the midline. The superior mesenteric vein (SMV) lies anterior to the truncated pancreas (P), whereas the superior mesenteric artery (SMA) lies posterior to it. **D.** CT scan obtained at the level of the right renal hilum reveals that the cecum (C) is located in the left lower quadrant. Notice the terminal ileum (TI) entering the colon. (From Fulcher AS, Turner MA: *Abdominal manifestations of situs anomalies in adults*. *RadioGraphics* 22:1439–1456, 2002.)

relationship of the superior mesenteric artery and superior mesenteric vein.⁶⁶

^{99m}Tc-labeled, heat-altered, autologous erythrocyte SPECT/CT is a reliable study to evaluate for functioning splenic tissue in the abdomen and pelvis.⁶⁷

POLYSPLENIA SYNDROME

Polysplenia syndrome, a heterotaxy syndrome characterized by multiple small spleens (Figs. 104-10 and 104-11), is referred to as situs ambiguus with left isomerism. In contrast to asplenia, it occurs equally in males and females, with some studies showing a female predilection to polysplenia. The reported incidence is 1 per 250,000 live births.⁵⁹ Polysplenia has a lower prevalence of congenital heart disease (50%-90%) and less severe defects than those with asplenia (Box 104-2).⁶⁸

Abdominal Radiologic Findings

In polysplenia, dextroposition of the stomach is present in approximately 45% of patients, and intestinal malrotation occurs in approximately 27%.⁶⁹ Polysplenia cannot be excluded solely on the basis of situs solitus.

Splenic tissue number and location are varied; 2 to 16 splenic nodules of approximately equal size can be found in the right

Figure 104-10 Polysplenia: gross specimen. Autopsy specimen of a patient with polysplenia shows multiple spleens.

Figure 104-11 Polysplenia: associated anomalies. Diagram shows the organ position in situs ambiguus with polysplenia. (From Fulcher AS, Turner MA: *Abdominal manifestations of situs anomalies in adults*. *RadioGraphics* 22:1439–1456, 2002.)

or left upper quadrant, depending on situs.⁷⁰ Ectopic splenic tissue may be difficult to characterize on a CT scan, and some patients may have poor splenic function. Splenic scintigraphy with ^{99m}Tc-labeled, heat-altered, autologous erythrocyte scintigraphy SPECT/CT is a sensitive method to detect functioning splenic tissue and correctly diagnose polysplenia.⁷¹

Polysplenia is associated with pancreatic abnormalities including short pancreas, dorsal agenesis, pancreas divisum, and annular or semiannular pancreas.⁷² Pancreatic development is closely associated with duodenal jejunal rotation, and pancreatic abnormalities are found to coexist with bowel malrotation and a preduodenal portal vein.⁷³

Biliary atresia is found to coexist with other congenital anatomic abnormalities in 20% of the cases. The most common is biliary atresia splenic malformation syndrome, and up to 90% are associated with polysplenia and gallbladder agenesis.⁷⁴ Magnetic resonance cholangiography with hepatocyte-specific gadolinium contrast agents has been shown to be superior to ^{99m}Tc-disofenin (DISIDA) hepatobiliary scintigraphy in the detection of biliary atresia.⁷⁵

BOX 104-2 DEVELOPMENTAL ANOMALIES WITH POLYSPLENIA SYNDROME

PULMONARY ANOMALIES

Bilateral morphologic left lung (bilobed) with bilateral hyparterial bronchi

CONGENITAL HEART MALFORMATIONS

Cardiac malposition

Dextrocardia

Great vessels

Subvalvar and valvar pulmonary or aortic obstruction or atresia

Cardiac defects

Absent coronary sinus

Absent atrial septum resulting in common atrium

Atrioventricular canal defects

Hypoplasia or absence of one ventricle

Double-outlet right ventricle

Venous system

Bilateral superior vena cava

Interrupted IVC with azygos continuation

Anomalous drainage due to an abnormal position of the atrial septum

Polysplenia is associated with absence (interruption) of the IVC between the renal and the hepatic veins, with independent drainage of the hepatic veins into the right atrium. The renal portion of the IVC receives blood return from both kidneys and passes posterior to the diaphragmatic crura to enter the thorax as the azygos vein (Fig. 104-12). The azygos vein joins the superior vena cava at the normal location in the right paratracheal space. Since the advent of cross-sectional imaging, azygos continuation of the IVC can be seen in otherwise asymptomatic patients without associated severe congenital heart disease and asplenia or polysplenia syndromes.⁷⁶ Sonography, CT, MRI, and angiography can confirm the diagnosis by showing the absence of the IVC between the renal and the hepatic veins with independent drainage of the hepatic veins into the right atrium.⁷⁷

Patients without cardiac anomalies may reach adulthood, accounting for 10% to 15% of cases of polysplenia. Because most adult patients do not exhibit any symptoms, polysplenia syndrome is often diagnosed incidentally during other procedures. Even adult patients can have anomalies in abdominal organs, including visceral heterotaxia with a right-sided stomach, left-sided or large midline liver, right-sided spleen, malrotation of the intestine, short pancreas, and anomalies of the IVC.⁷⁸

Polysplenia syndrome is recognized easily on diagnostic imaging, including a combination of abdominal ultrasonography, CT, and MRI. Identification of splenic tissue and location can serve as a landmark for detection and characterization of the subtypes of heterotaxy.⁷⁹

Multiple other malformations are associated with heterotaxy syndromes (Box 104-3).^{58-63,79-81}

Figure 104-12 Situs ambiguus with polysplenia in a 67-year-old man. **A.** Transverse contrast-enhanced CT scan of the abdomen shows a midline liver, multiple spleens (S) in the right upper quadrant adjacent to the collapsed stomach (St), and inferior vena cava interruption with azygos continuation (arrow). The low attenuation of the spleens is related to infarctions, which cause liquefaction and subcapsular hematomas. Notice the absence of splenic tissue in the left upper quadrant (asterisk). **B.** Transverse CT scan through the midabdomen reveals a midline gallbladder (GB). **C.** Transverse CT scan through the lower abdomen reveals the small bowel (SB) in the right lower quadrant and the colon in the left lower quadrant. The cecum (C) lies near the midline, a finding that indicates incomplete fixation. (From Fulcher AS, Turner MA: *Abdominal manifestations of situs anomalies in adults*. *RadioGraphics* 22:1439–1456, 2002.)

BOX 104-3 MALFORMATIONS ASSOCIATED WITH HETEROTAXY SYNDROMES

GASTROINTESTINAL TRACT

- Omphalocele
- Esophageal atresia and tracheoesophageal fistula
- Intestinal malrotation
- Duplication, hypoplasia, or angiodysplasia of the stomach
- Anal stenosis or atresia
- Aganglionic colon
- Duodenal atresia
- Gallbladder agenesis

PANCREAS

- Pancreas hypoplasia, (polycystic) malformations

LIVER

- Absence of the gallbladder
- Extrahepatic biliary atresia
- Polycystic liver
- Ectopic liver tissue in the adrenal glands

GENITOURINARY TRACT

- Renal agenesis or hypoplasia, cystic malformations
- Horseshoe kidney
- Duplicated collecting system
- Bilobed urinary bladder
- Urethral duplication or urethral valves
- Rectourethral fistula
- Bicornuate uterus
- Agenesis of the ovaries and ovarian cysts
- Duplicated, bicornuate or unicornuate uterus; vaginal atresia or duplication
- Testicular hypoplasia
- Penis duplication, hypospadias

RESPIRATORY TRACT

- Laryngeal cleft or hypoplasia
- Tracheoesophageal fistula, tracheal or esophageal atresia
- Pulmonary hypoplasia

CENTRAL NERVOUS SYSTEM

- Spine malformations, including midline abnormalities
- Dysgenesis or agenesis of the corpus callosum
- Porencephalic, cerebellar, or Dandy-Walker cysts
- Holoprosencephaly, hydranencephaly
- Cerebellar cysts
- Hypoplasia, dysplasia, or agenesis of the cerebellum
- Hydrocephalus
- Septum pellucidum abnormality
- Lumbar myelomeningocele
- Cleft lip or palate

MUSCULOSKELETAL

- Hypoplasia or dysostosis of cranial bones
- Overlapping toes, clubbed hands, polydactyly, absent radii
- Vertebral or rib anomalies
- Caudal regression, bifid sacrum, sacral agenesis

OTHER

- Fused or absent adrenal glands
- Single umbilical artery
- Diaphragmatic hernia

Although it is affected by many diseases, the spleen is not considered a great challenge to the radiologist.¹ In daily practice, the size and shape of the spleen typically are subjectively evaluated, and if there is no obvious splenomegaly or focal abnormality, the spleen usually is ignored. However, when abnormalities are detected, the radiologist plays an important role in providing a diagnosis and directing further clinical management.

Each imaging modality, including ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy, has specific advantages and limitations in

assessing the spleen. Plain radiographs of the abdomen can detect splenomegaly (Fig. 105-1) and splenic calcifications (Box 105-1) but otherwise do not have a significant diagnostic role. Currently, angiography is used only for therapeutic purposes, such as splenic embolization in trauma, hypersplenism, or rare vascular tumors.² ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG PET) combined with CT (FDG PET/CT) is becoming increasingly useful in the evaluation of malignant disease and has a high negative predictive value in predicting a malignant neoplasm in patients with solid-appearing splenic masses.³ Because of a perceived high risk of bleeding,

Figure 105-1 Massive hepatosplenomegaly.

A. Abdominal radiograph demonstrates a large soft tissue density in the left side of the abdomen that is displacing the splenic flexure of the colon inferiorly (arrow). **B.** The corresponding coronal reformatted CT image demonstrates the massively enlarged spleen that is displacing the stomach medially (short arrows) and the splenic flexure of the colon inferiorly (long arrow).

BOX 105-2 PATTERNS OF INVOLVEMENT IN SPLENIC PARENCHYMAL DISEASE

SOLITARY LESIONS

Solitary focus of any typically multifocal disease
Benign neoplasms: hemangioma, lymphangioma, hamartoma, inflammatory pseudotumor, peliosis, littoral cell angioma, sclerosing angiomatoid nodular transformation
Solitary pyogenic abscess

MULTIPLE FOCAL ABNORMALITIES

Trauma: lacerations, fractures, intrasplenic and subcapsular hematomas
Splenic rupture
Abscess: bacterial, fungal, granulomatous
Calcified granulomas
Sarcoidosis
Lymphangiomatosis, hemangiomatosis, peliosis
Lymphoma, lymphoproliferative disorders
Gaucher's disease
Metastatic disease
Hemangioma, hemangioendothelioma, peliosis

DIFFUSE DISEASE WITHOUT FOCAL LESIONS

Congestive disease: portal hypertension, splenic vein occlusion, or congestive heart failure
Inflammatory disease: various infections (e.g., tuberculosis) and inflammation (e.g., sarcoid)
Hyperplastic splenomegaly: hypertrophy resulting from removal of abnormal blood cells from the circulation (e.g., polycythemia vera)
Infiltrative (e.g., Gaucher's disease, hemosiderosis, malignant disease)

Modified from Paterson A, Frush DP, Donnelly LF, et al: A pattern-oriented approach to splenic imaging in infants and children. RadioGraphics 19:1465, 1999.

percutaneous biopsies of the spleen are not often performed in general practice. They are, however, relatively safe.⁴⁻⁶

The various imaging appearances and characteristics of benign and malignant splenic lesions are described in this chapter. Recognizing the range of the imaging and pathologic features of splenic abnormalities will narrow the differential diagnosis and help in planning further management.

A unique feature of the spleen on multidetector CT and MRI is the inhomogeneous enhancement pattern during the first minute after the intravenous administration of contrast material, which is most pronounced in the arterial phase (first 25-35 seconds). The enhancement pattern varies with different injection rates and tends to be more prominent in the presence of splenomegaly. These patterns have been described as serpentine, arciform, striped (i.e., zebra spleen), mottled, focal, and diffuse heterogeneity.⁷ This normal phenomenon is probably the result of differential flow through the vascular sinuses and cords of the red and white pulp.⁸ In most patients, this heterogeneity resolves after 60 to 70 seconds and should not be confused with disease.⁷⁻⁹ Keeping this phenomenon in mind, the

normal spleen should be homogeneous on all imaging modalities.

True lesions involving the spleen can be categorized as diseases manifesting with focal lesions, multifocal lesions, or a diffuse infiltrating pattern (Box 105-2).¹⁰ Although often asymptomatic, focal abnormalities must raise the suspicion of a pathologic condition.¹¹ Rarely, when the lesions are large, they may cause symptoms.

If the patient has a known disease, such as metastases, lymphoma, or tuberculosis, a general assumption is made that the focal abnormality represents splenic involvement. Ultimately, it is often the radiologist who has to decide whether further investigations are indicated or follow-up is more appropriate.

Splenunculi, Splenic Ectopia, and Splenosis

Splenunculi, also known as accessory spleens, splenules, and supernumerary spleens, are a common finding. They are found in approximately 10% to 30% of autopsies and in 16% of patients undergoing abdominal CT.^{12,13} The normal spleen is formed after multifocal development of splenic foci and subsequent fusion. Splenunculi are formed when one or more of these splenic foci fail to fuse.¹⁴

Accessory spleens are a few millimeters to several centimeters in the greatest diameter. They are typically supplied by branches of the splenic artery and demonstrate the same imaging and enhancement characteristics as normal splenic tissue. They are most commonly located medial to the spleen in or near its hilum (75%) and adjacent to the tail of the pancreas. Less common locations are within the pancreatic tail (17%), the gastrosplenic or splenorenal ligaments, the wall of the stomach or bowel, the mesentery or omentum, and the pelvis and scrotum (Fig. 105-2).¹⁵⁻¹⁷ Those found in the pancreatic tail are usually small and rarely noticed radiologically; if detected, they are often misdiagnosed as hypervascular tumors.^{18,19}

In patients with heterotaxia, left isomerism, or bilateral left-sidedness, many bilateral spleens or splenunculi may be present.^{20,21} Splenosis is autotransplantation of splenic tissue after disruption of the splenic capsule by trauma or surgery. Splenosis has been described in up to 74% of patients who underwent splenectomy after trauma, and it is often detected years after the initial trauma.²² These splenic implants closely resemble splenunculi on histologic examination, and distinction between these two conditions usually is not possible.^{14,23} Compared with accessory spleens, these implants are more numerous and variable in size and shape, and they are supplied by small perforating vessels arising at the site of implantation. They are typically located in the abdomen but may be found in various locations, including the pelvis, thorax, and scars.²⁴

Splenunculi and splenosis usually have little clinical significance, although there are exceptions.¹³ When splenectomy is

performed to control hematologic disorders such as idiopathic thrombocytopenic purpura or lymphoma, hypertrophy of an accessory spleen may cause or harbor the site of recurrent disease.²⁵ Accessory spleens also may mimic various pathologic conditions, such as lymphadenopathy, tumors associated with surrounding organs (e.g., pancreas, adrenal, kidney), abdominal and pelvic masses, endometriosis, and metastases. Rarely, splenunculi may be manifested with nonspecific abdominal pain or become symptomatic when they undergo torsion, cyst formation, or hemorrhage.²⁶⁻³⁰

RADIOLOGIC FINDINGS

On ultrasound, accessory spleens are well-circumscribed, round or oval nodules with an echogenicity identical or slightly hypoechoic to that of the adjacent spleen (Fig. 105-3A). Seventy-five percent demonstrate acoustic enhancement or an incomplete hyperechoic rim, or both.²²

MR images of accessory spleens demonstrate signal intensity and enhancement similar to those of the normal spleen on all sequences (Fig. 105-3B). On CT, accessory spleens are well-marginated, rounded, homogeneously enhancing lesions (Fig. 105-3C). Attenuation of small accessory spleens (<1 cm) is often somewhat less than that of the spleen because of partial volume effects.¹³

Heat-denatured red blood cell scintigraphy is considered the best study for detection of an accessory spleen because of its high sensitivity and specificity.^{31,32} Denatured red blood cells are labeled with technetium Tc 99m pertechnetate, after which single photon emission CT imaging is performed. On this examination, the round to ovoid foci with avid tracer uptake are seen colocalizing to the nodules seen on CT.

^{99m}Tc-sulfur colloid scans are less commonly used to evaluate splenic disorders, but they are less accurate than heat-denatured red blood cell scans in the detection of splenunculi.³³ Radioimmunoscinigraphy of the spleen provides no additional diagnostic information over heat-denatured red blood cell scintigraphy of the spleen in detecting splenunculi.³²

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of supernumerary spleens includes lymphadenopathy, abdominal and pelvic masses, endometriosis, masses associated with surrounding organs (e.g., pancreas, adrenal, kidney), peritoneal mesothelioma, and metastases. Imaging characteristics similar to those of the normal spleen

Figure 105-2 Splenogonadal fusion in a 4-year-old boy.

Figure 105-3 Accessory spleen and splenosis.

A. Ultrasound demonstrates a well-circumscribed, round nodule (arrow) with echogenicity similar to that of the adjacent spleen. **B.** Axial view, liver acquisition with volume acceleration (LAVA) MRI after gadolinium enhancement obtained in the portal venous phase demonstrates a well-circumscribed nodule medial to the spleen (arrow) with the same signal intensity and enhancement as the splenic parenchyma. **C.** Contrast-enhanced CT shows two nodular lesions (i.e., splenosis) in the left upper abdomen in a patient with a history of splenectomy after a traumatic splenic injury.

and heat-denatured red blood cell scintigraphy permit differentiation from other disorders.

Hemangioma

EPIDEMIOLOGY AND PATHOGENESIS

Hemangioma is the most common benign neoplasm of the spleen, found in approximately 0.3% to 14% of autopsy specimens.^{34,35} Hemangiomas primarily affect young to middle-aged adults, but they are found in all age groups.³⁵ Some investigators report predominance in males, whereas others did not find a gender predilection.^{34,36-37} Hemangiomas typically are found incidentally on radiologic imaging or pathologic studies. On occasion, they are multiple or diffuse, a condition called hemangiomatosis, or they are part of generalized angiomatosis, such as Klippel-Trénaunay-Weber syndrome.³⁸

CLINICAL FINDINGS

Patients with hemangiomas are generally asymptomatic.³⁷ Rarely, large hemangiomas or hemangiomatosis may be manifested with a palpable mass in the left upper quadrant, pain, or splenomegaly. Kasabach-Merritt syndrome, characterized by hemangiomatosis, thrombocytopenia, and intravascular coagulation, is a rare syndrome resulting from sequestration of red blood cells and platelets and consumption of clotting factors in the hemangiomas typically seen in early infancy.^{39,40}

Spontaneous splenic rupture of splenic hemangiomas is extremely uncommon.⁴¹ Resection should be reserved for the rare situations, such as untreatable pain, diagnostic uncertainty, or compression of adjacent organs.³⁵

PATHOLOGY

On gross examination, hemangiomas appear blue to red and spongy, and they are typically well circumscribed.⁴² Most splenic hemangiomas are cavernous and a few are capillary or may demonstrate both features.³⁴ On histopathologic examination, they are nonencapsulated proliferations of vascular channels of various sizes lined by a single layer of plump endothelial cells with little intervening fibrous tissue filled with red blood cells.^{14,42} Small hemangiomas of the spleen are typically homogeneously solid, although larger ones may demonstrate multiple cystic spaces of various sizes.⁴³ They may contain calcifications.⁴⁴ Diffuse hemangiomatosis is a rare, benign neoplastic condition in which the entire spleen is replaced by neoplastic blood vessels interspersed with sparse connective tissue.^{40,42,45}

RADIOLOGIC FINDINGS

The imaging appearance of splenic hemangiomas depends on the gross morphology and is a spectrum from solid to mixed to purely cystic.⁴⁵ Findings on abdominal radiographs are usually normal, but a large hemangioma may be manifested as a soft

tissue mass in the left upper quadrant. If calcifications are present, they can be punctate or curvilinear.³⁴

On ultrasound, small splenic hemangiomas appear as discrete echogenic lesions similar to those in the liver (Fig. 105-4).⁴⁶ Large hemangiomas may appear as complex masses with both solid and cystic areas.⁴⁷ Acoustic shadowing due to calcifications may be seen.

Hemangiomas may be manifested as solid, homogeneous masses or complex cystic masses with slight hypodensity on nonenhanced CT scans.^{44,47-49} Punctate, peripheral, and curvilinear calcifications may be present. Other splenic hemangiomas may appear cystic or heterogeneous, depending on the

extent of the cystic and solid components. On contrast-enhanced CT, hemangiomas of the spleen may demonstrate a progressive centripetal enhancement pattern and become isodense on the delayed images, as can be seen in liver hemangiomas (Fig. 105-5A, B) although this occurs less frequently in the splenic hemangiomas than with hepatic hemangiomas. This probably reflects the differences in vascular supply of the liver and spleen.^{34,36,50}

On MR studies, splenic hemangiomas are isointense to hypointense on the T1-weighted images and typically hyperintense on the T2-weighted images compared with the normal spleen (Fig. 105-5C).³⁵ Ramani and coworkers³⁶ demonstrated

Figure 105-4 Splenic hemangioma. **A.** Longitudinal ultrasound image shows a well-defined, hyperechoic lesion. **B.** Corresponding contrast-enhanced CT demonstrates a hypodense lesion with some faint peripheral enhancement in the portal venous phase (arrow).

Figure 105-5 Multiple splenic hemangiomas.

A. Contrast-enhanced CT in the portal venous phase demonstrates multiple, homogeneous, hypodense splenic lesions. **B.** Complete fill of the lesions is shown on a 10-minute delayed image. **C.** The lesions are homogeneously hyperintense on the T2-weighted MR image. CT and MRI demonstrated progressive centripetal enhancement.

in a study of 22 hemangiomas that 19 were hyperintense, two were isointense, and one was hypointense relative to the spleen on T2-weighted images. In the same study, a progressive centripetal pattern of enhancement was observed in 19 of 22 hemangiomas on the dynamic gadolinium-enhanced series, and 19 hemangiomas demonstrated uniform enhancement on the delayed images. Other types of enhancement that can be observed are immediate homogeneous and persistent enhancement on the delayed images and a peripheral centripetal enhancement with a persistent lack of central enhancement on delayed images.^{36,51} Sometimes, a central fibrous scar may demonstrate persistent enhancement.⁵² Cavernous hemangiomas typically demonstrate heterogeneous enhancement; the cystic components do not demonstrate enhancement on contrast-enhanced CT and MRI.⁵⁰

There is a paucity of published data regarding scintigraphy of splenic hemangiomas, and the results are often based on criteria used for the liver.⁵³ ^{99m}Tc-sulfur colloid scintigraphy of the liver and spleen may demonstrate a photopenic defect in the spleen.⁴⁴ ^{99m}Tc-labeled red blood cell scans demonstrate a hypovascular area on the blood flow images; early blood pool images may reveal a hypovascular lesion or demonstrate some pooling of tracer activity. Typically, the hemangiomas demonstrate increased activity on the delayed images, giving a perfusion-blood pool mismatch. This phenomenon is considered pathognomonic of hepatic hemangiomas.^{53,54}

Angiographic findings of splenic hemangiomas are variable and nonspecific. They can be hypovascular or hypervascular, with or without pooling of contrast material and with or without abnormal tumor vessels.⁴⁴

Hamartoma

EPIDEMIOLOGY AND PATHOGENESIS

Hamartoma of the spleen is a rare, benign tumor first described by Rokitsansky in 1859 as a splenoma.⁵⁵ Hamartomas are also known as a spleen within a spleen, post-traumatic scars, nodular hyperplasia, and hyperplastic nodules. They are usually discovered incidentally during diagnostic imaging, splenectomy, or autopsy.^{56,57} Most are described in case reports or small series. The reported incidence in large autopsy and splenectomy series varies from 0.12% to 0.17%.⁵⁸⁻⁶⁰ The definitive diagnosis of a splenic hamartoma is rarely made on the basis of imaging. Hamartomas are often confirmed by pathologic evaluation after splenectomy.^{60,61}

No gender predilection has been demonstrated for hamartomas, and they can be found in any age group. Most hamartomas are solitary. Hamartomas of the spleen have been associated with hematologic disorders, tuberous sclerosis, malignant neoplasms, and Wiskott-Aldrich-like syndrome.^{56,57,60,62}

CLINICAL FINDINGS

Hamartomas are usually discovered incidentally, and most patients are asymptomatic, but a large hamartoma may be manifested as a palpable mass or splenomegaly. Rupture of a splenic hamartoma is rare.⁶³ Splenic hamartomas can be associated with hematologic disorders, including pancytopenia, anemia, and thrombocytopenia. This association probably results from sequestration of the hematopoietic cells in the abnormal vascular spaces. Resolution of these hematologic disorders after

hamartoma resection has been reported.^{62,64} Associated growth retardation and recurrent infections have been reported in the pediatric population.⁵⁶ It can be difficult, especially by cytologic analysis, to differentiate a hamartoma from a malignant neoplasm. Resection—partial or total splenectomy—is often performed because of diagnostic uncertainty.^{60,61,65,66}

PATHOLOGY

On gross examination, hamartomas are well-circumscribed, solid lesions that compress the surrounding parenchyma. They vary in size from less than 1 cm to more than 20 cm in diameter.⁵⁶ On histologic examination, splenic hamartomas are composed of disorganized red pulp elements with reticuloendothelial cell proliferation. Normal white pulp is usually absent.^{14,34,42,66} They contain a mixture of unorganized sinus-like structures lined by endothelial cells surrounded by fibrotic cords of predominant splenic red pulp without a true capsule.^{34,42} Cystic spaces and coarse calcifications have been reported.³⁴ Special immunohistochemical techniques can be used to differentiate hamartomas from hemangiomas. The etiology of splenic hamartomas is controversial; some authors consider splenic hamartomas to be congenital in origin, whereas others consider hamartomas to be true neoplasms or to be an acquired proliferative process.^{42,60}

RADIOLOGIC FINDINGS

On sonography, hamartomas are typically well-defined, homogeneous masses (Fig. 105-6A). The reported appearance varies from isoechoic to mildly hyperechoic or hypoechoic.⁶⁷⁻⁶⁹ The mass may contain cystic areas or coarse calcifications.^{68,70} On color Doppler images, the mass often demonstrates increased blood flow.^{67,69} Some investigators report that sonography is more sensitive than CT in depicting hamartomas of the spleen.⁷⁰

A contour abnormality is often the only visible finding on CT (Fig. 105-6B).³⁴ A typical hamartoma is isodense or mildly hypodense on nonenhanced and on intravenously enhanced CT scans (Fig. 105-6C).⁷¹ Heterogeneous enhancement can be observed in larger lesions; uniform and prolonged contrast enhancement is often shown on the delayed images.⁷²

On MRI, hamartomas are well-defined, isointense masses on the T1-weighted images. In a series of five patients, four were imaged with T2 sequences. In three of these, the lesions were heterogeneously hyperintense, and in one, the mass was hypointense relative to the normal spleen.³⁶ In the same series, all hamartomas demonstrated diffuse, heterogeneous enhancement in the early phases and became more uniformly enhanced on delayed images on dynamic contrast-enhanced sequences. Similar MRI characteristics were described by other investigators, including prolonged enhancement on the delayed images after intravenous administration of gadolinium.⁷¹⁻⁷³

Angiography, sometimes performed for preoperative embolization, may demonstrate a hypervascular mass with peripheral tumor vessels and tumor stains.^{56,67,74,75}

The literature describing scintigraphic imaging findings for splenic hamartomas is sparse. Case reports of splenic hamartomas describe hot spots on ^{99m}Tc-sulfur colloid scintigraphy, presumably caused by uptake in reticuloendothelial cells.^{75,76} The dynamic images of radiocolloid scans may show increased flow in the spleen. Other studies have described decreased

Figure 105-6 Hamartoma. **A.** Longitudinal ultrasound image demonstrates a mildly hypoechoic mass medial to the spleen with some internal color flow. **B.** Unenhanced CT shows a round mass involving the medial portion of the spleen, and it is isodense compared with the splenic parenchyma (there is a metallic artifact from a surgical clip from remote gastric surgery). **C.** Contrast-enhanced CT obtained during the portal venous phase demonstrates the mass with the same enhancement pattern, with two small, hypodense cystic areas anteriorly.

uptake of the radiocolloid tracer compared with the normal spleen.⁷⁰

Although splenic hamartoma may be suspected on the basis of the imaging characteristics, a definitive diagnosis can rarely be made by the imaging findings alone.^{34,60} A definitive diagnosis may be established with a percutaneous biopsy, although this often proves to be a challenge for the pathologist, and more often, splenectomy is needed for a definitive diagnosis.^{4,66,77}

Lymphangioma

EPIDEMIOLOGY AND PATHOGENESIS

Splenic lymphangiomas are rare, benign, slow-growing, congenital neoplasms.⁷⁸⁻⁸⁰ They are typically seen in childhood, with only a few reported cases in adults. Splenic lymphangiomas can be isolated solitary lesions within the spleen, or the entire spleen may be replaced (i.e., splenic lymphangiomatosis).⁷⁸ This may be part of a rare congenital malformation of the lymphatics called lymphangiomatosis.⁸¹ Lymphangiomatosis predominantly affects pediatric patients and typically involves multiple organs and locations, including the neck, mediastinum, and retroperitoneum.^{78,81} Lymphangiomas of the spleen have also been associated with Klippel-Trénaunay-Weber syndrome.⁸²

CLINICAL FINDINGS

In adults, splenic lymphangiomas are often asymptomatic.⁸⁰ When symptoms are present, they are usually related to the increased size of the spleen and include left upper quadrant

pain, nausea, and abdominal distention.^{34,83} Associated coagulopathy, hypersplenism, and portal hypertension have been described.^{84,85} Physical examination may reveal a tender mass in the left upper quadrant.⁸⁰

Management varies from conservative treatment for small, asymptomatic lesions to partial or total splenectomy for large, symptomatic lesions.^{83,86} Subtotal splenic embolization is also described as an effective treatment option.⁷⁸

PATHOLOGY

On gross examination, splenic lymphangiomas typically are subcapsular, multicystic lesions filled with watery pink proteinaceous fluid.¹⁴ On histologic evaluation, they are composed of multiple, thin-walled cysts of various sizes lined with a flat endothelium. Lymphangiomas often involve the capsule and trabeculae, where lymphatic structures are normally present.⁴² Lymphangiomas are traditionally classified as capillary, cavernous, or cystic, depending on the histologic findings.^{81,87}

RADIOLOGIC FINDINGS

Findings on plain radiographs are usually normal, but they may demonstrate splenomegaly with a mass effect on adjacent viscera. Curvilinear calcifications can be present.³⁴

Ultrasound typically shows multiple cysts that are a few millimeters to several centimeters in diameter and are divided by thin septations (Fig. 105-7).^{80,84,88} Splenic lymphangiomas may have calcifications, and the finding of internal echoes depends on the presence of proteinaceous or hemorrhagic fluid.

Figure 105-7 Lymphangiomatosis in a young female patient involving multiple organs, including the spleen. Longitudinal image demonstrates an enlarged spleen with numerous cystic lesions; sizes range from a few millimeters to several centimeters.

Vascularity within the walls and the septa can be demonstrated with color Doppler imaging.⁸⁵

CT can reveal subcapsular, low-density, nonenhancing, sharply marginated, thin-walled cysts. Small, curvilinear or punctate calcifications may be observed.^{34,78} After administration of an intravenous contrast agent, the septa may demonstrate enhancement.^{80,88}

MRI reveals multiple, well-defined cysts within the spleen. They appear hypointense on T1-weighted images and hyperintense on the T2-weighted sequences.^{34,88} The cysts may demonstrate high signal intensity on the T1-weighted images if they contain proteinaceous or hemorrhagic fluid.⁴³ The septa appear as hypointense structures on the T2-weighted sequences.⁸⁹ These septa are usually better defined on contrast-enhanced CT and MR images.

When the lymphatic spaces are small, as in capillary lymphangiomas, the lesion may have a solid appearance on radiologic imaging, making a correct preoperative radiologic diagnosis difficult.⁹⁰ The literature on angiographic and scintigraphic findings in splenic lymphangiomas is limited. Lymphangiomas do not demonstrate uptake of the radiopharmaceutical on ^{99m}Tc-sulfur colloid scintigraphy.⁸²

On angiography, splenic lymphangiomas have been observed as round or oval, hypovascular mass lesions displacing the surrounding arterial branches without neovascularity.⁸⁶ With more extensive involvement, many focal lucencies of various sizes can be seen in the venous phase, producing the so-called Swiss cheese appearance.^{86,91}

Inflammatory Pseudotumor

EPIDEMIOLOGY AND PATHOGENESIS

Splenic inflammatory pseudotumor is a rare, benign lesion. Although the cause and pathogenesis are unknown, it is thought that inflammatory pseudotumors result from an unusual, non-specific, inflammatory reparative response to injury such as infection.^{42,92-94}

CLINICAL FINDINGS

Like most other benign splenic tumors, inflammatory pseudotumors are usually asymptomatic. In the typical scenario, this lesion is discovered incidentally, sometimes presumed to represent lymphoma. Fever and leukocytosis are the most commonly described associated symptoms.⁹² If the pseudotumor is large, a palpable mass may be discovered on physical examination.

PATHOLOGY

On gross examination, the lesions are often well defined and white. On histopathologic examination, the lesions are found to be well circumscribed and composed of spindle cells and various proportions of mixed inflammatory cells, including small lymphocytes, plasma cells, and histiocytes. A zonal distribution is characteristic, with central foci of necrosis and hemorrhage, foamy histiocytes, granulomas, and giant cells.^{95,96} Calcifications can be present.

RADIOLOGIC FINDINGS

Unfortunately, radiologic imaging techniques do not permit preoperative diagnosis of these lesions. Splenic inflammatory pseudotumors are typically misdiagnosed as other masses, such as lymphoma or metastatic disease.^{92,94}

Abdominal radiographs are of limited utility. Ultrasound usually demonstrates a well-defined hypoechoic mass and acoustic shadowing when calcifications are present.⁹²

Unenhanced CT scans reveal a rounded mass with low attenuation with or without calcifications. Enhancement can be homogeneous or heterogeneous, and delayed enhancement patterns are often described.⁹³ Central, stellate, low-density areas may persist within the mass, probably corresponding to focal areas of fibrosis.⁹⁷

On MRI, these lesions appear isointense to the splenic parenchyma on T1-weighted images. Both heterogeneously hypointense and hyperintense lesions compared with normal spleen tissue have been described on T2-weighted images.^{93,94} As with CT, most investigators describe a peripheral enhancement pattern with gradual, delayed central enhancement from the periphery to the center on the dynamic sequences.^{93,94,98}

Peliosis of the Spleen

EPIDEMIOLOGY AND PATHOGENESIS

Splenic peliosis is a rare condition characterized by sinusoidal dilation and formation of multiple, cystlike, blood-filled cavities within the parenchyma.⁹⁹ This condition most commonly affects the liver, but any organ, including the spleen, can be affected. Splenic peliosis as an isolated finding is rare; it is usually associated with hepatic peliosis.¹⁰⁰ The pathogenesis of splenic peliosis is unclear. Splenic peliosis has been associated with various conditions, including infection, hematologic malignant neoplasms, use of anabolic steroids, and immunocompromised states.

CLINICAL FINDINGS

Patients with splenic peliosis are often asymptomatic, and the condition is found incidentally on imaging studies or at autopsy.

However, peliosis can be manifested with spontaneous splenic rupture.¹⁰¹ The first well-documented case of peliosis was reported in 1866, when Cohnheim described a spontaneous splenic rupture in a young man with peliosis.¹⁰²

PATHOLOGY

On gross examination, the size of the spleen is often found to be normal. Multiple, blood-filled cavities are round to oval and are 1 mm to several centimeters in diameter. The blood-filled cystic spaces may be arranged sporadically, may occur in clusters, or may be disseminated throughout the spleen.³⁴ Thrombosis may occur in the cystic spaces. On microscopic examination, the cysts located within the red pulp are lined with flattened, sinusoidal endothelium, or they may lack a clear cell lining.^{42,99}

RADIOLOGIC FINDINGS

No large series of splenic peliosis are available. The imaging findings are typically described in publications of hepatic peliosis and in case reports. The imaging findings of peliosis are variable and depend on the size of the cysts and whether there is thrombosis of the cystic contents.¹⁰³

Sonography typically reveals multiple, poorly defined, hypoechoic lesions. The lesions may be hyperechoic if thrombosis is present.³⁴

On unenhanced CT, peliosis lesions usually appear as multiple areas of low attenuation. On contrast-enhanced CT scans, splenic peliosis most commonly is manifested as multiple, small, well-defined, hypoattenuating, cystlike lesions.^{34,101} High-attenuation lesions and fluid-fluid levels, which are thought to reflect a hematocrit effect, demonstrating enhancement in their dependent portions have also been described.^{104,105}

The signal intensities of the lesions on MRI depend on the age and status of the blood components. On T2-weighted sequences, these lesions are usually hyperintense. On T1-weighted sequences, the lesions are typically hypointense or isointense to the normal spleen. After gadolinium injection, peliotic lesions may or may not enhance.¹⁰⁴ Various patterns of enhancement have been described.

Angiography may reveal areas of pooling of contrast material and distortion of the intrasplenic vessels.¹⁰⁶ If the lesions rupture, perisplenic hematoma, splenic laceration, and intraperitoneal hemorrhage may be evident.^{101,106}

Cystic Splenic Lesions

Cystic lesions of the spleen are relatively uncommon compared with the frequency with which cysts are encountered in other solid abdominal organs. The reported incidence of splenic cysts at autopsy is approximately 7.6 per 10,000 people.¹⁰⁷ The true incidence is probably higher; in one series, the incidence was approximately 1% detected with abdominal ultrasound.¹¹

A wide variety of lesions may be manifested as splenic cysts (Table 105-1). In Western countries, most splenic cysts are asymptomatic and discovered incidentally during routine abdominal imaging or autopsy. The most common splenic cysts in the Western world are congenital and traumatic in origin. Worldwide, parasitic cysts (most are echinococcal) are much more common and account for approximately 70% of splenic cysts.¹⁰⁸ The correct cause and pathophysiologic mechanism of

TABLE 105-1 Cystic Lesions of the Spleen

Type of Lesion	Examples
Congenital	Epidermoid cysts (primary, true, mesothelial) Dermoid (rare)
Acquired	Pseudocysts (secondary cysts): postinflammatory, post-traumatic, postinfarction, pancreatic
Infection	Parasitic: echinococcosis Abscess: pyogenic, fungal
Neoplastic	Benign: cystic hemangioma, cystic hamartoma, cystic lymphangioma, peliosis Malignant: angiosarcoma, lymphoma, metastases

a splenic cyst can often be suggested by the medical history, symptoms, and appearance of the cyst on imaging.⁴³

CONGENITAL CYSTS AND PSEUDOCYSTS

Epidemiology and Pathogenesis

Traditionally, nonparasitic, non-neoplastic splenic cysts have been grouped as true cysts and pseudocysts on the basis of a classification system developed in 1940 by Fowler.^{109,110} Congenital cysts, also known as true, primary, epidermoid, or mesothelial cysts, have an epithelial or mesothelial cell lining and are thought to be developmental in origin. Pseudocysts, also known as secondary cysts or false cysts, do not have an epithelial lining.

Congenital cysts are believed to be the result of embryonic inclusions of splenic capsular mesothelial cells into the splenic parenchyma with subsequent gradual growth, although numerous other theories have been postulated.^{14,42,111} Congenital cysts account for approximately 10% of all splenic cysts, and they are not associated with cysts in other organs.^{107,112} Congenital cysts are often discovered in children and young adults, but they are found in all age groups, and they have a female predominance.¹¹³⁻¹¹⁵ A rare familial occurrence of splenic epidermoid cysts has also been reported.^{112,116} Dermoid cysts of the spleen are rare and have been described in only a few case reports.¹¹⁷

Pseudocysts are thought to be the result of an intrasplenic hematoma, infarct, or infection, although a history of trauma or infection is often not apparent. They are more common in females, often discovered in young adults, but they can be found in all age groups.^{113,114} Most primary or secondary splenic cysts are located in the superior portion, but they can be found anywhere in the spleen.¹¹³

Although Fowler's categorization of splenic cysts is widely accepted, Morgenstern has made a case against the traditional classification of true and false cysts and argued that it is much more likely that most cysts are congenital in origin. He reasoned that a history of significant trauma is rarely obtained and that hemorrhagic cystic lesions after a known trauma usually have a different appearance. With the current practice of nonoperative management of splenic injuries, there should have been a significant rise in the incidence of splenic cysts. He stated that it can be difficult to identify an epithelial lining in splenic cysts and that this probably led to the erroneous classification of many reported cysts as pseudocysts.¹¹⁴

The natural history of splenic cysts is unknown. No long-term follow-up reports of patients with splenic cysts have been published.¹¹²

Figure 105-8 Pseudocyst.

A. The abdominal radiograph demonstrates a round, calcified lesion in the left upper abdomen.

B. Unenhanced CT shows a homogeneously hypodense lesion (15 HU) with a thin, calcified wall.

Clinical Findings

In Western countries, virtually all splenic cysts are asymptomatic and found during routine imaging.¹¹⁵ Symptoms may occur when the cysts are large and include left upper quadrant discomfort, fullness, and pain.^{113,114} Complications, such as spontaneous hemorrhage, rupture, or secondary infection, are rare.¹¹⁸⁻¹²⁰ If the cyst is large, physical examination may reveal splenomegaly or a palpable mass with or without tenderness.¹¹² Results of routine laboratory tests usually are normal, although epidermoid cysts of the spleen have been associated with elevated levels of cancer antigen 19-9 and carcinoembryonic antigen.¹²¹

In our opinion, small and asymptomatic cysts are best managed conservatively. Treatment of large and symptomatic cysts includes percutaneous aspiration with or without sclerotherapy and partial splenectomy.^{114,115,122}

Pathology

In the series of Dachman and colleagues,¹¹³ true and false cysts could not be differentiated on the basis of gross appearance. True cysts are typically unilocular, and they have a trabeculated, shiny, pearly white lining. The fluid may be clear or turbid, and the color can be yellow, green, or brown, containing cholesterol or blood degradation products.^{14,42,114} On microscopic examination, the epithelial lining is variable, and a stratified squamous epithelium is the most common finding.¹²³ On occasion, septations or thick, partially calcified walls can be seen.^{42,113} When inflammation or hemorrhage occurs in these cysts, the cellular lining may be replaced by nonspecific fibrous or granulation tissue, and histologic distinction between epidermoid cysts and pseudocysts becomes difficult.

Most pseudocysts are unilocular and have a smooth inner surface. The wall is formed by fibrous tissue with or without calcified components, and these cysts are often filled with serous or hemorrhagic fluid.^{14,42,115}

Radiologic Findings

It is not possible to distinguish between true and false cysts with any imaging technique.^{43,113} The wall of a pseudocyst tends to be thicker. If a cyst is large, it may be identified on plain radiographs. In certain instances, it may be possible to

differentiate a cyst from splenomegaly by the observation of a round mass with a normal, intact splenic tip.¹¹³ Curvilinear calcifications may also help identify the presence of a splenic cyst (Fig. 105-8).

On ultrasound, splenic cysts, like cysts elsewhere in the body, characteristically appear as anechoic lesions with smooth borders and demonstrate increased through-transmission (Fig. 105-9A). Epidermoid cysts and pseudocysts may demonstrate septations, thick walls, trabeculations, internal echoes, and calcified walls.¹¹³

On CT, splenic cysts appear as homogeneous, well-defined, round or oval, low-enhancing or nonenhancing, hypodense lesions (Fig. 105-9B). The attenuation values typically range from 0 to 15 HU. Higher attenuation values are found in the presence of protein or blood degradation products. The cyst wall can be thick or partially calcified, and septations are sometimes observed.^{43,113}

On MRI, splenic cysts demonstrate low signal intensity on the T1-weighted images and high, uniform signal intensity on the T2-weighted images (Fig. 105-9C).^{51,124,125} Complicated cysts, because of the presence of proteinaceous fluid or hemorrhage, may demonstrate high signal intensity on the T1-weighted images and mixed signal intensity on the T2-weighted images. Cysts should not demonstrate any enhancement after the administration of gadolinium.

On scintigraphy, if the cyst is large enough, a solitary photopenic defect may be seen. Splenic cysts are avascular on angiography.¹¹³

HYDATID DISEASE

Epidemiology and Pathogenesis

Hydatid disease, or echinococcosis, is a zoonotic tapeworm infection caused by the species *Echinococcus granulosus*. The larva, known as the hydatid, forms a cyst as it develops in the lung, liver, kidney, or spleen. The disease involves the spleen in approximately 2.5% to 6% of patients with abdominal hydatidosis and typically occurs in patients living in or emigrated from endemic areas.¹²⁶⁻¹²⁹ Splenic hydatid involvement is usually part of more widespread abdominal disease after rupture of a hydatid liver cyst. Primary echinococcal involvement of the spleen is rare.¹⁰⁸ Alveolar echinococcal

Figure 105-9 Congenital cyst: small, simple asymptomatic cyst in a young female patient. **A.** The sonogram shows an anechoic lesion with smooth borders and increased through-transmission. **B.** Contrast-enhanced CT demonstrates a well-defined, round, nonenhancing, hypodense cystic lesion. **C.** Axial, fast spin-echo, fat saturation MRI demonstrates small, round lesion with uniform high signal intensity on the T2-weighted image.

disease is caused by *Echinococcus multilocularis* and rarely involves the spleen.¹³⁰

Pathology

The hydatid cyst wall has three layers. The larvae of the tapeworm incite an inflammatory host response that forms an outer layer of inflammatory cells and fibrous tissue called the pericyst. The true cyst wall, also called the endocyst, is composed of an outer laminated membrane lined by an inner germinal layer made up of daughter cysts, also called the brood capsules. Scolices develop on the inner aspect of the brood capsules and after separation of the cyst wall form a sandlike material within the cysts.^{42,129,131} When the parasites die, the cysts become inactive, and the cysts may calcify and undergo fibrosis.

Clinical Findings

Splenic hydatidosis is often asymptomatic. Symptoms, if present, include abdominal pain and splenomegaly.^{108,128} More often, the clinical and radiologic findings are nonspecific, and the diagnosis should be suspected in all patients from endemic areas presenting with a splenic cyst.

Large cysts may cause compression of surrounding structures. Complications include infection, cyst rupture, and fistulization to surrounding organs.¹²⁸ Rupture into the abdominal cavity may result in an anaphylactic reaction and the spread of multiple cysts throughout the abdomen.¹³² Serologic tests have a sensitivity of approximately 90% in diagnosis of hydatid disease.¹³³ The imaging findings, combined with the clinical, serologic, and epidemiologic results, usually provide the correct diagnosis.^{134,135}

Albendazole is the mainstay of echinococcal treatment. Splenic hydatid cysts can be treated percutaneously with cyst aspiration and injection of hypertonic saline solution or alcohol, also known as the PAIR technique (i.e., puncture, aspiration, injection, reaspiration).¹³⁵⁻¹³⁷ Splenectomy or partial splenectomy can be performed if other treatment options have failed. Inactive cysts are typically observed and managed conservatively.

Classification

A World Health Organization Working Group on echinococcosis formulated a standardized sonographic classification of echinococcal cysts (Table 105-2).^{134,138}

The classification is intended to follow the natural history of cystic hydatid disease. Type CL cysts are usually seen at an early stage of development and are not fertile. These cysts cannot be differentiated from nonparasitic splenic cysts on the basis of imaging. Because the origin is uncertain, this cyst is not given the designation of a cystic echinococcosis (CE) type of lesion and is recorded as a cystic lesion (CL). The CE 1 and CE 2 types are active, usually fertile cysts containing viable protoscoleces. CE 3 cysts are degenerative and are entering a transitional stage. Most CE 4 and CE 5 cysts are inactive, nonfertile cysts.

Radiologic Imaging

The radiologic appearance of hydatid cysts reflects the natural history of the disease, in which daughter cyst formation is part

of the natural aging process. The imaging findings are variable and range from purely cystic to solid-appearing pseudotumors, depending on the stage of the disease (see Table 105-2). All of these characteristic imaging appearances are lost when the cysts become infected.

Plain radiographs are of limited utility. Curvilinear or ring-like calcifications, representing calcifications of pericysts, could suggest cystic echinococcosis, especially in patients from endemic areas.¹³⁹

Ultrasound is the most popular and readily available technique worldwide for evaluation of abdominal echinococcal disease. Ultrasound is used for diagnosis, therapeutic decision-making, and follow-up. Portable ultrasound is also used in remote areas to screen, to diagnose, and to treat patients.¹³⁵

Fine internal echoes within the cysts may be seen because of shifting of the brood capsules, often called hydatid sand (i.e., the snowflake sign). Wavy bands of detached, laminated endocysts (i.e., the water lily sign) may be observed within the cysts. Daughter cysts may partially or completely fill the mother cyst (Fig. 105-10A). Calcifications, varying from tiny to massive, are often present.

CT and MRI are indicated for patients not suited for ultrasound and for evaluation of widespread or complicated disease. Cross-sectional imaging is helpful in planning percutaneous therapy or surgery. Subtle cyst wall calcifications are best demonstrated with CT.

On CT, a hydatid cyst may be manifested as a well-defined, hypoattenuating cystic lesion with water-attenuation values and a distinguishable wall. Coarse wall calcifications are often present. The hydatid cysts can be hyperdense because of debris, hydatid sand, and inflammatory cells. In CE 2 cysts, the round daughter cysts are arranged at the periphery, or they completely fill the mother cysts. CT attenuation of the daughter cysts is typically lower than that of the mother cysts. Type CE 3 lesions appear as relatively high attenuation, round or oval masses with scattered calcifications and occasional daughter cysts (Fig. 105-10B). Type CE 4 cysts may appear as a complex mass. The septa and cyst wall frequently enhance after the intravenous administration of contrast material.¹²⁹ Type CE 5 cysts are complex cystic or solid-looking lesions, and they can be partially or completely calcified.

On MRI, the simple cysts are hypointense on the T1-weighted images and markedly hyperintense on the T2-weighted images.

Classification	Description
CL	Simple cystic lesion; no cyst wall visible
CE 1	Unilocular simple cyst with visible cyst wall; may exhibit "hydatid sand," fine internal echoes due to shifting of the brood capsules (i.e., snowflake sign)
CE 2	Multivesicular, multiseptate cyst; daughter cysts may partially or completely fill the mother cyst; septations may produce wheel-like structures; contained daughter cysts may produce a rosette-like or honeycomb-like structure
CE 3	Unilocular, anechoic content with detachment of the laminated membrane from the cyst wall, visible as a floating membrane (i.e., water lily sign), or complex masses caused by unilocular cysts containing daughter cysts and echoic areas
CE 4	Heterogeneous hypoechoic or inhomogeneous degenerative contents; no daughter cysts; degenerating membranes may produce a ball of wool sign
CE 5	Cysts with a thick, calcified, arch-shaped wall; lesions are partially or completely calcified

CE, Cystic echinococcosis; CL, undifferentiated, simple cystic lesions. Modified from WHO Informal Working Group: International classification of ultrasound images in cystic echinococcosis for application in clinical and field epidemiological settings. *Acta Trop* 85:253–261, 2003.

Figure 105-10 Echinococcal cyst: cystic echinococcosis type 3. **A.** Longitudinal ultrasound image of the spleen demonstrates a complex lesion with central hyperechoic areas and small peripheral daughter cysts. **B.** Contrast-enhanced CT during the arterial phase demonstrates an oval mass involving the medial portion of the spleen with relatively high central attenuation and a few peripheral hypodense daughter cysts. There is associated involvement of the right adrenal. (Courtesy M. de Jonge, MD, Amsterdam, The Netherlands.)

A low signal intensity rim (i.e., the rim sign), which is more evident on T2-weighted MR images, has been described as characteristic of hydatidosis.¹³¹ The septa and cyst wall frequently enhance after the intravenous administration of gadolinium. The daughter cysts may appear hypointense or isointense relative to the maternal matrix on T1- and T2-weighted images. The collapsed parasitic membranes may reflect a serpent sign or snake sign. These membranes have low signal intensity on all sequences. Type CE 4 and CE 5 cysts usually are hypointense on T1- and T2-weighted images.

The presence of a cystic lesion in a patient from an endemic area with positive serologic test results most likely indicates hydatid disease. In almost all cases of splenic hydatid cystic disease, hydatid liver disease coexists. The presence of daughter cysts is probably the most helpful imaging feature.

DIFFERENTIAL DIAGNOSIS OF CYSTIC SPLENIC MASSES

The differential diagnosis of cystic splenic masses is extensive (see Box 105-2) and includes true or false splenic cysts, parasitic (hydatid) cysts, pseudocysts related to pancreatitis, pyogenic abscess, benign tumors of the spleen (e.g., hemangiomas, hamartomas, lymphangiomas, lymphoma), and metastatic tumors. The correct diagnosis can usually be suggested by an analysis of clinical findings and symptoms, the medical history, and the appearance of the cyst.

Splenic cysts (true or false) are the most common in Western countries. They are typically well defined, are of homogeneous water density, and have a thin or imperceptible wall. After infection or hemorrhage, the cysts become more complex.

The presence of a cystic lesion with wall calcification and daughter cysts in a patient from an endemic area should raise the suspicion of cystic echinococcosis. Most cases of splenic hydatid cystic disease have coexisting hydatid liver disease.

Patients with a splenic abscess usually are sick or septic, and they present with fever, left upper abdominal pain, and leukocytosis. A cystic splenic mass developing in a patient with pancreatitis is likely to be a pancreatic pseudocyst.

Benign splenic neoplasms (e.g., hemangioma, lymphangioma, hamartoma) may show single or multiple cystic spaces in the mass that rarely fulfill the criteria for a simple cyst. Splenic lymphoma may be manifested as ill-defined, hypoechoic masses with internal echoes on ultrasound or as low-density lesions with or without a thick rim on CT scans, mimicking a cystic lesion.^{140,141} Cystic metastases to the spleen have been reported from melanoma and adenocarcinoma of the breast and ovary, but they usually occur in the setting of widespread metastatic disease and typically have a complex appearance. Isolated splenic metastases are rare.

Splenic Infection and Inflammatory Disease

Inflammation and infection of the spleen are manifested in three distinct patterns: generalized splenomegaly without discerning focal lesions; solitary lesions; and a diffuse, miliary or macronodular pattern with or without splenomegaly.¹⁰ Generalized splenomegaly is a nonspecific finding and can be found in a variety of diseases, including infections and inflammatory diseases (Box 105-3). Multiple splenic nodular lesions, usually

BOX 105-3 COMMON CAUSES OF DIFFUSE SPLENOMEGALY

Congestive splenomegaly
 Portal hypertension
 Splenic vein thrombosis
 Congestive heart failure
 Infectious and inflammatory diseases
 Acute infections (e.g., infectious mononucleosis)
 Chronic infections (e.g., miliary tuberculosis, malaria)
 Sarcoidosis
 Systemic lupus erythematosus
 Hyperplastic splenomegaly (i.e., hypertrophy)
 Hemolytic anemias (e.g., malaria, polycythemia vera)
 Infiltrative splenomegaly
 Lymphomas, leukemias
 Metastases
 Extramedullary hematopoiesis
 Storage diseases (e.g., Gaucher's disease, amyloidosis)
 Splenic neoplasms
 Lymphangiomatosis
 Hemangiomatosis
 Peliosis

 Hodgkin's lymphoma
 Non-Hodgkin's lymphoma
 Metastases

*Splenic nodules are less than 2 cm in diameter.

smaller than 2 cm in diameter, are commonly associated with nonbacterial infections, such as fungal and granulomatous infections. An abscess may be manifested as a solitary lesion. The presence of gas in a lesion, although rare, is pathognomonic of a pyogenic infection.

SPLENIC NODULAR DISEASE

Multiple, small, nodular splenic lesions are encountered in a wide variety of diseases (Box 105-4). These consist of bacterial, fungal, and protozoal infections; granulomatous diseases, including mycobacterial infections; and sarcoidosis and malignant neoplasms, such as lymphoma and metastases. Many patients with multiple splenic nodules have an established diagnosis, such as lymphoma, metastases, or tuberculosis. In these cases, the nodules are presumed to represent the same disease, and pathologic confirmation is usually not necessary. Multiorgan involvement is typical, and similar changes are seen in the liver and other organs.

If no diagnosis has been established and the splenic nodules are an isolated finding, the diagnosis can rarely be made on the

imaging findings alone. The different causes are often manifested in a clinically similar fashion, typically with splenomegaly and fever. The history and clinical presentation may narrow the differential diagnosis. Additional investigations, such as laboratory tests (including tumor markers), tuberculosis testing, and bone marrow biopsies, may be indicated. When the underlying disease is successfully treated, the nodules usually resolve or become calcified granulomas.

The imaging characteristics of the various nodular conditions are nonspecific and similar. The nodules are often numerous and are a few millimeters up to 2 cm in diameter. They are hypoechoic on ultrasound and hypoattenuating on CT. The lesions appear hypointense on T1-weighted sequences and vary from hypointense to hyperintense on the T2-weighted sequences. The nodules usually do not enhance or may show ring enhancement after intravenous administration of contrast material. Healed granulomas appear as scattered, discrete, small calcifications in an otherwise normal spleen.

FUNGAL ABSCESS AND MICROABSCESS

Fungal infections of the spleen typically occur in immunocompromised patients with neutropenia. Acquired immunodeficiency syndrome (AIDS), chemotherapy, immunosuppressive agents, and lymphoproliferative disorders are the most common risk factors.¹⁴²⁻¹⁴⁴ Hepatosplenic fungal infection is found in approximately 7% of patients with acute leukemia, and these patients have a poor prognosis.^{143,144} *Candida* is the fungal organism most frequently encountered, followed by *Aspergillus*, *Cryptococcus*, and *Histoplasma*.¹⁴⁵

When the host response improves, the focus of candidiasis becomes encapsulated and walled off by neutrophils and inflammatory cells. As a result, the findings on diagnostic imaging are often normal in patients with chronic disseminated candidiasis because the characteristic changes become visible only when the neutrophil count recovers.¹⁴⁶⁻¹⁴⁸ In an analogous case, the phenomenon of waning of focal hepatic and splenic lesions on imaging during neutropenia was described by Pestalozzi.¹⁴⁹

No single imaging technique has proved to be specific and sensitive in patients with suspected or proven fungal infections, and only serial imaging may be able to detect hepatosplenic involvement.¹⁴⁸ Regardless of the imaging findings, a biopsy may be necessary to establish the final diagnosis because blood cultures are often falsely negative, particularly with *Candida* infections.¹⁵⁰

Pathology

On histologic examination, these lesions are poorly confined, containing pseudohyphae and yeast forms. On microscopic examination, the lesions are multilayered, consisting of an outer ring of fibrosis, a middle area of inflammatory cells, and a central area of necrosis.¹⁴⁷

Clinical Findings

The most common manifestation of systemic candidiasis is persistent fever not responsive to conventional antibiotics.¹⁴⁴⁻¹⁴⁸ The clinical diagnosis of fungal infection is often difficult because the presenting symptoms may be similar to those of the patient's primary disorder: fever and splenomegaly. Unexplained clinical deterioration in an immunosuppressed patient should raise the suspicion of a disseminated fungal infection.

Radiologic Findings

The limitation of all imaging modalities in the diagnosis of hepatosplenic fungal disease is the inability to visualize fungal lesions during the neutropenic phase. It is important to consider repeating the studies after recovery of the neutrophil count, especially if the clinical suspicion is high and the patient is not responding to conventional antibiotic therapy.¹⁵¹

Different sonographic patterns of hepatosplenic candidiasis have been described. Multiple, small, hypoechoic nodules are the most common finding (Fig. 105-11A).¹⁴² A less common appearance can be seen in the early course of infection and has been described as the wheel-within-a-wheel appearance (i.e., the target sign). It is caused by a peripheral hypoechoic zone of fibrosis, the first wheel, and an echogenic second wheel of inflammatory cells around a central echogenic nidus containing necrosis and fungal elements (Fig. 105-11B).^{152,153} This type of

Figure 105-11 Dissemminated *Candida* infection in a patient with acute myelogenous leukemia. **A.** Transverse ultrasound image shows multiple, small, hypoechoic lesions in the splenic parenchyma. **B.** Sonogram with a high-frequency (5-12 MHz) linear transducer demonstrates a small, hypoechoic nodule with a central echogenic nidus. **C.** Contrast-enhanced CT shows numerous, subcentimeter, hypodense nodular lesions throughout the liver and spleen.

lesion may evolve into a bull's-eye lesion, which histologically corresponds to inflammatory cells surrounded by fibrosis. Late in the disease with healing, lesions usually become small and hyperechoic with various degrees of posterior acoustic shadowing, with or without calcification, or they may disappear.^{142,152} The use of higher frequency, linear array transducers significantly improves lesion detection.¹⁵⁴

On CT, fungal microabscesses are typically 5- to 10-mm, hypodense, nodular lesions (Fig. 105-11C). The detection rate is low (30%) on noncontrast scans.¹⁵⁵ In the arterial phase (25-35 seconds), most lesions (70%) demonstrate an enhancing peripheral ring that typically disappears in the portal venous phase.¹⁵⁶ In the study by Metser and associates,¹⁵⁵ the detection rate of about 90% was not significantly different between the arterial phase and portal venous phase. Similar findings are typical for the liver and sometimes for the kidneys.¹⁵³

Rudolph and colleagues¹⁵⁶ demonstrated another appearance in approximately 30% of patients. In the arterial phase, these lesions showed an inhomogeneous central enhancement surrounded by a double target ring consisting of a hypodense inner ring surrounded by a hyperdense outer ring. Over time, contrast enhancement is in a centrifugal direction, and the lesions appear smaller or disappear in the portal venous phase.

MRI is superior to CT and ultrasound for identification of hepatosplenic fungal disease, with a reported sensitivity of 100% and specificity of 96%.^{144,151} MRI is especially useful for following the course of infection during antifungal therapy and for evaluating the response to treatment.¹⁴⁵

On MRI, in the acute phase of hepatosplenic fungal disease, the lesions are small, measuring less than 1 cm in diameter. They are mildly hypointense on the T1-weighted images and markedly hyperintense on the T2-weighted images.

In the subacute phase, the lesions tend to be mildly hyperintense on both T1- and T2-weighted sequences.^{151,153} A peripheral ring of very low signal intensity is typical on all sequences in the subacute phase.¹⁵¹ The central region of the lesions may demonstrate enhancement after gadolinium administration, with the peripheral ring continuing to have low signal intensity, making them more visible. The time for transformation from acute to subacute lesions is 2 weeks to 3 months.¹⁴⁵

After successful antifungal treatment, the 1- to 3-cm lesions become irregular, and the central area disappears. The time to appearance of healed fungal foci on MRI ranges from 3 months to more than 1 year.¹⁵⁷

^{99m}Tc-sulfur colloid liver-spleen, indium In 111-labeled leukocyte, and gallium Ga 67 scans usually are not helpful in detecting microabscesses because normal uptake of the radio-tracer obscures the small lesions. Results of ⁶⁷Ga scans are variable and may show multifocal areas of increased or decreased uptake in the spleen.¹⁵⁸

FDG PET scans show increased ¹⁸F-fluorodeoxyglucose uptake. This represents a promising imaging technique in patients at high risk for infections, although published data regarding fungal infections are still limited.¹⁵⁹

TUBERCULOSIS

Mycobacterium tuberculosis is an important health problem in developing countries; in Western countries, it is typically seen in immunocompromised patients.¹⁶⁰ Splenic tuberculosis usually occurs in the setting of disseminated, miliary infection and is manifested as multiple splenic nodules between 0.2 and

1 cm in diameter. Macronodular presentation is rare.¹⁶¹ In cases of disseminated, miliary pulmonary tuberculosis, splenic involvement has been found in 80% to 100% at autopsy. Associated findings include lymphadenopathy and a hypoechoic pattern on ultrasound or central low attenuation on CT, which is more commonly seen in patients with *Mycobacterium avium* complex infection (Fig. 105-12).¹⁶²

MYCOBACTERIUM AVIUM COMPLEX INFECTION

Mycobacterium avium complex infections of the spleen, also called *Mycobacterium avium-intracellulare* infections, are typically seen in immunocompromised patients, such as those with AIDS. Splenomegaly with multiple, low-attenuation nodules can be seen on imaging (Fig. 105-13). Associated findings, such

Figure 105-12 Disseminated miliary tuberculosis. Contrast-enhanced CT demonstrates multiple hypodense nodules. Notice the associated para-aortic and retrocrural hypodense lymphadenopathy (arrow).

Figure 105-13 *Mycobacterium avium* complex infection. Longitudinal sonogram demonstrates splenomegaly with multiple, small, hypoechoic nodules.

as marked hepatic and splenic enlargement, diffuse jejunal wall thickening, and enlarged lymph nodes, suggest disseminated *M. avium* complex infection.^{163,164} Patients with *M. avium* complex infection tend to have more homogeneous lymph nodes compared with those with tuberculosis, but a tissue diagnosis is mandatory.

PNEUMOCYSTIS JIROVECI PNEUMONIA

Pneumocystis jiroveci pneumonia, formerly known as *Pneumocystis carinii* pneumonia, is the most common opportunistic infection in patients with AIDS. Extrapulmonary involvement causes necrotizing granulomas. Intrasplenic *P. jiroveci* infection is often discovered incidentally in patients with AIDS undergoing diagnostic imaging for a fever of unknown origin.¹⁶⁵ When it is treated successfully, the nodules may enlarge and become progressively calcified in a rimlike or a punctate fashion.^{166,167} On ultrasound, the findings include splenomegaly with small, hypoechoic lesions with cystic components or tiny, highly reflective, nonshadowing foci or calcified granulomas (Fig. 105-14).¹⁶⁵ The nodules are hypodense on CT or manifested as calcified granulomas in the later stages of disease.^{168,169}

CAT-SCRATCH DISEASE

Cat-scratch disease is a self-limited infection by *Bartonella henselae* that occurs after being scratched by a domestic cat. It affects an estimated 22,000 people in the United States each year, and most are children and adolescents.¹⁷⁰ Hepatosplenic involvement is uncommon, but *B. henselae* infection should be considered in a patient with fever of unknown origin, abdominal pain, and multiple hypodense lesions in the liver and spleen.^{171,172}

Figure 105-14 *Pneumocystis jiroveci* pneumonia. Longitudinal ultrasound image demonstrates multiple, punctate calcifications after successful treatment.

SARCOIDOSIS

Sarcoidosis is a systemic disease of unknown cause characterized by formation of noncaseating, epithelioid granulomas. Sarcoidosis most commonly affects the lungs and intrathoracic lymph nodes, but any organ system can be involved.¹⁷³ Splenomegaly, typically associated with hepatomegaly and abdominal lymphadenopathy, is usually mild and seen in 25% to 60% of these patients.¹⁷⁴⁻¹⁷⁶ Massive splenomegaly (>18 cm long) is seen in approximately 6% of patients with sarcoidosis.¹⁷⁷

Histologic evidence of liver and spleen involvement is seen in up to 77% at autopsy, but it is a relatively uncommon finding at diagnostic imaging.¹⁷⁷ On imaging, splenic nodules are seen in 6% to 33% of patients with sarcoid.¹⁷⁴⁻¹⁷⁶ In one study, these patients typically presented with hepatosplenomegaly, abdominal lymphadenopathy, and symptoms such as abdominal pain, fatigue, and malaise.¹⁷⁷ In the same study, the nodules were not associated with advanced lung disease and did not indicate a change in chest radiographic stage. The infradiaphragmatic adenopathy in sarcoidosis tends to be small and discrete, and retrocrural adenopathy is uncommon in these patients compared with patients with lymphoma. There is, however, a significant overlap in appearance and distribution of the lymph nodes in lymphoma and sarcoidosis, and these criteria cannot be used for accurate disease characterization.¹⁷⁶

The nodules in sarcoid are 0.1 to 3.0 cm in diameter.¹⁷⁸⁻¹⁸⁰ On ultrasound, the nodules have been described as hypoechoic to slightly hyperechoic or inhomogeneous.^{177,180} On CT, the nodules are hypodense relative to adjacent normal spleen after intravenous administration of a contrast agent (Fig. 105-15).^{178,179} The nodules are hypointense on all MR sequences and best seen on early-phase, gadolinium-enhanced, T2-weighted, fat-suppressed images or on T1-weighted sequences.¹⁷⁷ The nodules do not enhance after intravenous administration of contrast material on CT or MRI.

Figure 105-15 Sarcoidosis. Contrast-enhanced CT obtained in the portal venous phase shows numerous hypodense nodules.

LYMPHOMA OR METASTATIC DISEASE

Lymphomas—typically small cell lymphomas and mantle cell lymphomas and, less frequently, Hodgkin's lymphoma—can be manifested with multiple, nodular splenic lesions or with a miliary pattern. Nodules resembling those found in sarcoidosis have been described in patients with Hodgkin's lymphoma.^{42,181} This finding is usually part of disseminated disease including lymphadenopathy. Isolated splenic lymphoma is rare.^{14,42}

Metastatic disease to the spleen may be manifested as solitary or multiple nodules, rarely in a miliary pattern. This typically occurs in patients with advanced disease and widespread involvement of other organs.

GAMNA-GANDY BODIES

Gamna-Gandy bodies are siderotic nodules caused by focal organized hemorrhagic infarcts. They are typically seen in patients with congestive splenomegaly and sickle cell disease. They were also described in patients with hemolytic anemia, leukemia, lymphoma, or acquired hemochromatosis and in patients receiving multiple blood transfusions.^{182,183} The siderotic nodules occur in 9% to 12% of patients with portal hypertension and are not related to the degree of splenomegaly.^{182,184} On histologic examination, the nodules are small, yellow or brown, fibrotic lesions containing hemosiderin and calcium and sometimes containing foreign body giant cells.

Gamna-Gandy bodies are best seen by MRI as multiple, 3- to 8-mm, markedly hypointense nodules on T1-weighted and T2-weighted images.¹⁸² The gradient recalled echo sequence is the most sensitive for detection of hemosiderin and these nodules.¹⁸²⁻¹⁸⁴ Nodule conspicuity increases after gadolinium enhancement on the T1-weighted, gradient recalled echo images (Fig. 105-16). Gamna-Gandy bodies do not enhance.

Figure 105-16 Gamna-Gandy bodies in a patient with cirrhosis and portal hypertension. Portal venous phase, axial, T1-weighted FAME (fast acquisition with multiphase enhanced fast gradient recalled echo with three-dimensional Fourier transformation) MR image after gadolinium enhancement demonstrates numerous, small, hypointense nodules throughout the spleen.

Ultrasound is less accurate than MRI. In a study by Chan and associates,¹⁸⁵ ultrasound detected the nodules in 24 of 34 patients, with a sensitivity of 70.6% and a specificity of 78.9%. Gamna-Gandy bodies appear as multiple, punctate, hyperechoic foci.

Unenhanced CT may detect Gamna-Gandy bodies as multiple, faint, hyperdense nodules shown by the calcifications within them.¹⁸⁶ However, the nodules often are not detected on CT.¹⁸⁴

PYOGENIC ABSCESS

Epidemiology and Pathogenesis

An isolated splenic abscess is a rare entity, with a reported incidence in autopsy series between 0.14% and 0.7%.¹⁸⁷⁻¹⁸⁹ However, splenic abscesses are becoming more common as a result of an increasing number of immunosuppressed patients, patients with AIDS, and injection drug abusers.¹⁹⁰ Pyogenic splenic abscesses are usually solitary and unilocular or multilocular, but they can also be multifocal.

Most abscesses are caused by disseminated infection and are seen in patients with sepsis and septic emboli.^{190,191} Less common routes are contiguous infection (e.g., infected pancreatitis, perinephric abscess) and superinfection after an underlying splenic injury (e.g., trauma, infarct). In approximately 20% of cases, no source or cause is discovered.¹⁹¹ Roughly one third of patients have other concurrent extrasplenic abscesses. The reported mortality rate for splenic abscess in the literature is about 10%.^{191,192} Multiple splenic abscesses, gas-containing abscesses, and gram-negative bacillus infection are poor prognostic factors.^{191,193} Depending on the underlying disease, a variety of microorganisms may be encountered, including gram-negative bacilli (e.g., *Klebsiella pneumoniae*), gram-positive cocci, fungi, polybacteria, and mycobacteria.^{192,193}

Clinical Findings

The most common clinical presentations in patients with splenic abscesses are fever (92%), left upper abdominal pain (77%), and leukocytosis (66%).¹⁹⁴ Other symptoms include left pleural effusion and splenomegaly. Diabetes, immunosuppression, or immunodeficiency is often a contributing factor.¹⁹⁵

Early diagnosis of a splenic abscess with identification of organisms and determination of sensitivity is essential for effective antibiotic treatment. In small abscesses, percutaneous diagnostic aspiration can be performed. For larger abscesses, percutaneous drainage procedures have become the treatment of choice, allowing preservation of the spleen.^{4,5,196,197} Splenectomy is reserved for complicated cases. Complications of splenic abscesses include rupture and peritonitis with potential life-threatening results.

Radiologic Findings

The appearance of a splenic abscess depends on the stage of development. In the early phase, there is an ill-defined mass that later develops into a complex collection with septations and debris and that sometimes contains gas.¹⁹⁴ When a capsule has developed, the lesion becomes well defined. Splenic abscesses can be solitary and unilocular, solitary and multilocular, or multifocal.¹⁸⁷ The infecting organism cannot be predicted on the basis of imaging appearances.

The most frequent plain radiographic finding in splenic abscess is a left pleural effusion (42%), followed by an infiltrate

in the left lung base (20%) and splenomegaly.¹⁹¹ A splenic abscess is rarely identified by extraluminal gas or air-fluid levels in the left upper quadrant on plain films.

Ultrasound has a sensitivity of 75% to 98% in detecting a splenic abscess.^{187,191,198} Sonography is especially useful as a screening examination for bedridden patients, for patients with renal impairment, and for evaluation of small splenic lesions. In some patients, the examination may be technically difficult because of overlying gas from the bowel or lung. The sonographic appearance of a splenic abscess depends on the stage of development, and a typical pattern is encountered in only 44% of cases.¹⁹³ In the early phase, there is an ill-defined, hypoechoic lesion mimicking a mass. Later, the abscess may develop into an anechoic cysts or a complex cystic lesion with septa, debris, and acoustic shadowing caused by gas (Fig. 105-17A).¹⁹⁴ When a capsule has developed, the lesion is typically well defined with a thin, hyperechoic rim.

On CT, a splenic abscess typically is manifested as a unilocular or multilocular, hypodense collection or complex cystic lesion with an enhancing rim after intravenous administration of contrast material (Fig. 105-17B). CT can be diagnostic if the collection contains gas, but this is a rare finding.¹⁹⁶

The advantages of CT are high sensitivity (92%-98%), non-invasiveness, and speed.^{187,191} CT aids in differentiating unilocular from multilocular abscesses, is excellent for exact localization, and provides better anatomic information about the perisplenic area. This information can then be used to guide further management (Fig. 105-17C). CT may reveal concurrent areas of infection and can help detect the underlying source of disease.

MRI is not often performed in the work-up of patients with splenic abscesses because CT is highly sensitive, and many patients are not clinically stable. Splenic abscesses are hypointense on the T1-weighted images and mildly to moderately hyperintense on the T2-weighted images compared with the normal spleen; they demonstrate minimal to intense peripheral enhancement after intravenous administration of gadolinium.^{51,124}

Nuclear medicine plays a limited role in the detection and localization of splenic abscesses. If the abscess is more than 2 cm in diameter, ^{99m}Tc-sulfur colloid scans of the liver and spleen may demonstrate a nonspecific splenic filling defect. The ⁶⁷Ga scan and the ¹¹¹In-labeled leukocyte scan may show increased accumulation of radionuclide in the spleen. However, normal, inherent splenic activity on ⁶⁷Ga scans and ¹¹¹In-labeled leukocyte scans typically obscures an inflammatory focus within or near the spleen, resulting in a false-negative examination finding. A ⁶⁷Ga scan is nonspecific because tracer uptake is also seen in neoplastic lesions, particularly in lymphomas.¹⁸⁸ A ^{99m}Tc-sulfur colloid scan of the liver and spleen before injection of ¹¹¹In-labeled leukocytes appears to improve detection and characterization compared with performing ¹¹¹In-tagged leukocyte scans alone.^{188,199} FDG PET/CT is helpful in detecting a site of infection; however, its role in diagnosis of a focal splenic abscess has not been evaluated.^{3,159}

Angiography is sometimes used for management of vascular complications. Intrasplenic mycotic aneurysms are rare and described only in case reports.²⁰⁰ If angiography is performed,

Figure 105-17 Splenic abscess (methicillin-resistant *Staphylococcus aureus*) in a patient with endocarditis. **A.** Ultrasound demonstrates a complex cystic lesion with debris. **B.** Contrast-enhanced CT shows a large, unilocular, hypodense collection with a mildly enhancing rim. **C.** Contrast-enhanced CT after successful percutaneous pigtail drainage shows almost complete resolution. (Courtesy H. L. S. Go, MD, Alkmaar, The Netherlands.)

the abscess appears as a mass with attenuated vessels and a hypervascular rim.

Splenic Infarction

EPIDEMIOLOGY AND PATHOGENESIS

Splenic infarction, the result of arterial or venous compromise, has many potential causes, including hematologic disorders, thromboembolic disease, vascular diseases, and trauma (Box 105-5). Although splenic infarction is a relatively common finding, only a few larger series have been published, and most of the literature consists of case reports.²⁰¹⁻²⁰³

The cause of splenic infarcts tends to vary with age. Patients younger than 40 years most often have an associated hematologic disorder, and those older than 41 years more often have an embolic event.²⁰¹ Overall, hematologic disorders, including sickle cell disease, are probably the most common cause of splenic infarction.

Infarcts may be segmental or massive, involving the entire organ. Because the branches of the splenic artery are end arteries, occlusion leads to focal splenic infarction.¹⁰ Complications of splenic infarction occur in 7% to 20% of patients and include abscesses, pseudocysts, hemorrhage, subcapsular hematoma, and rupture.²⁰⁴⁻²⁰⁶

CLINICAL FINDINGS

The most common manifestation is pain in the left upper abdomen and fever.²⁰⁷ Associated findings include pleuritic chest pain, referred pain to the left shoulder, and

leukocytosis.^{201,202,207} However, 30% to 50% of patients remain asymptomatic.^{207,208} Symptoms may develop when complications occur, such as abscess formation or hemorrhage.

PATHOLOGY

All infarcts are initially hemorrhagic; over time, they become pale with hyperemic borders; and finally, they become fibrotic.⁴² On histologic examination, most infarcts caused by emboli have a wedge-shaped, pale appearance, with the base at the capsular surface.¹⁴ In the course of healing, the infarcts may completely resolve or leave atrophic, fibrotic tissue with or without calcifications. Small emboli may produce a miliary or nodular pattern, resulting in a spotted spleen. Infarcts in patients with massive splenomegaly or caused by an infiltrative process often do not have the typical wedge-shaped appearance.

RADIOLOGIC FINDINGS

The classic radiologic appearance of a splenic infarct is a wedge-shaped area with the base at the splenic capsule and the apex pointing toward the hilum (Fig. 105-18). However, the radiologic appearance of splenic infarcts varies and includes a multinodular or mottled appearance and a masslike appearance with irregular margins (Fig. 105-19).²⁰⁹ In the subacute phase, when the infarct organizes, the affected area usually becomes better defined. In time, the changes may completely resolve, or the infarcted area may show atrophic changes with or without calcifications.²¹⁰ In rare cases, the entire spleen may undergo infarction, leaving only a thin rim of normal, enhancing parenchyma along the outer margin because of preserved capsular vessels.^{10,211}

The sonographic findings reflect the variable anatomic-pathologic manifestations, and a wide range of appearances can be seen, including single or multiple, wedge-shaped or round, and hypoechoic, anechoic, and hyperechoic lesions (Fig. 105-20A).^{208,212} In the acute phase, the infarct tends to be hypoechoic, peripheral, and wedge shaped or round. The lesion may become better defined during the course of several days. In the chronic

Figure 105-18 Chronic splenic infarct. Contrast-enhanced CT demonstrates a classic wedge-shaped, peripherally nonenhancing, hypodense area. The base of the infarct is at the splenic capsule, and the apex points toward the hilum. Some volume loss and capsular retraction indicate a chronic infarct.

Figure 105-19 Acute splenic infarct. **A.** Contrast-enhanced CT demonstrates a round infarct in a patient with a mycotic aneurysm of the celiac axis (arrow). Many similar lesions throughout the spleen were seen (not shown). **B.** Contrast-enhanced CT in a different patient demonstrates a mottled appearance of the splenic infarcts with associated perisplenic fluid.

Figure 105-20 Subacute splenic infarct. **A.** The sonogram shows an ill-defined, hypoechoic area with the apex pointing toward the hilum. **B.** Contrast-enhanced CT at a comparable level demonstrates a nonenhancing, hypodense area. **C.** Axial-view, T2-weighted MR image shows a predominantly high signal intensity area in the same patient.

stage, splenic infarcts appear as areas of increased echogenicity that represent fibrotic scar.

Although the infarcts can sometimes be detected on noncontrast CT scans, enhanced CT markedly improves visualization. On CT, the findings vary from the classic wedge-shaped, peripherally nonenhancing, hypodense area (Fig. 105-20B) to the heterogeneously hypodense, ill-defined, masslike lesion.^{206,209,213} In the hyperacute phase, CT may show areas of mottled increased

attenuation, representing hemorrhagic areas. In the subacute phase, infarcts tend to become better demarcated. In time, the findings vary and include complete resolution, persistent changes, and progressive volume loss with capsular retraction due to focal fibrosis.²⁰⁶

On MRI, the signal intensity of infarcted areas depends on the age of the infarct and the degree of the hemorrhagic component.²¹⁴ Acute and subacute infarcted areas usually appear as

diffuse low signal intensity on the T1-weighted images and as inhomogeneously high signal intensity on the T2-weighted images (Fig. 105-20C). The area does not enhance after intravenous administration of contrast material, although similar to what can be visualized on enhanced CT, capsular enhancement can be seen on MRI.^{214,215}

An infarct is manifested as a focal area of diminished activity on splenic scintigraphy, but this is a nonspecific finding.²¹⁵ No uptake of the radiotracer in the spleen may be observed with massive infarction.²¹⁶ Alternatively, a ^{99m}Tc-labeled, heat-denatured red blood cell scan may be used to demonstrate viable splenic tissue that is not evident on CT, MRI, or ^{99m}Tc-sulfur colloid scintigraphy.²¹⁷

Angiography demonstrates wedge-shaped regions of decreased perfusion or nonvisualization of the spleen in cases of complete infarction.²⁰⁶

The imaging findings of complicated splenic infarction include progressive liquefaction necrosis with outward expansion, subcapsular hemorrhage, splenic rupture with free blood in the peritoneal cavity, and locules of intraparenchymal gas, indicating a superimposed infection.^{208,218} Intraparenchymal splenic gas may be found after therapeutic splenic embolization, and only 17% of these patients prove to have an infection.²¹⁹

Nontraumatic Splenic Rupture

Nontraumatic splenic rupture, also called spontaneous splenic rupture or pathologic splenic rupture, is a rare but potentially life-threatening condition. Nontraumatic splenic rupture has been described in a wide variety of medical conditions (Box 105-6). The diseased spleen is often enlarged, and there is no history of trauma. However, insignificant activities, such as coughing, sneezing, or vomiting, have been described as possible triggers in splenic rupture.²²⁰ Spontaneous rupture of a normal spleen is even more uncommon.²²¹ In patients with splenic disease, the spleen is more prone to rupture because of the altered consistency and the splenomegaly that extends the spleen below the rib cage.²²² Other than the apparent mechanism, the clinical, pathologic, and imaging findings are the same as those seen in traumatic rupture of the spleen (Fig. 105-21).

Splenomegaly

There are numerous causes of diffuse splenic enlargement, and there are various ways of classifying splenomegaly (see Box 105-3). Splenomegaly can be categorized on the basis of pathogenesis. Congestive splenomegaly is the result of portal hypertension, splenic vein occlusion, or congestive heart failure. Inflammatory splenomegaly develops in association with various infections and inflammatory processes and results from an increase in the immune response with resultant lymphoid hyperplasia (e.g., infectious mononucleosis). Hyperplastic splenomegaly is caused by hypertrophy resulting from the removal of abnormal blood cells from the circulation (e.g., polycythemia vera). Infectious splenomegaly, the result of splenic filtering of blood-borne pathogens, may lead to microabscess formation (e.g., mycobacterial infection). Infiltrative splenomegaly is the result of engorgement of macrophages with indigestible materials (e.g., Gaucher's disease, amyloidosis, malignant disease).

On imaging, the average adult spleen is less than 11 cm long, less than 7 cm wide, and less than 5 cm thick. The spleen has an average weight of 150 g, with a range between 80 and 300 g. The normal spleen decreases in size and weight with advancing age.^{223,224} On radiographs, splenomegaly can be detected as a soft tissue mass in the left upper quadrant, displacing the stomach medially and the splenic flexure of the colon inferiorly (see Fig. 105-1). Ultrasound, CT, and MRI are accurate in determining the size and volume of the spleen.²²⁵⁻²²⁷ The length of the spleen (on ultrasound in the right lateral decubitus position) can be used to accurately diagnose splenomegaly.^{225,228}

Miscellaneous Disorders

SICKLE CELL DISEASE

Epidemiology and Pathogenesis

Sickle cell disease, also called sickle cell anemia, is an autosomal recessive disorder affecting red blood cells. A mutation in the hemoglobin A (HbA) gene leads to formation of an abnormal hemoglobin molecule (HbS). Patients may be heterozygotes

Figure 105-21 Spontaneous splenic rupture in a patient with malaria. Contrast-enhanced CT demonstrates a subcapsular hematoma (short arrows) and a linear, hypodense parenchymal defect (long arrow).

Figure 105-22 End-stage spleen in a patient with homozygous sickle cell disease.

A. Unenhanced CT shows a small and densely calcified spleen.
B. ^{99m}Tc -sulfur colloid scan of the liver and spleen demonstrates no uptake of the radiotracer, which is consistent with functional asplenia (arrow). (Courtesy R. Attariwala, MD, PhD, Vancouver, Canada.)

(i.e., sickle cell trait), with one normal HbA gene (*HBA1* or *HBA2*) and one abnormal HbS gene, or homozygotes, with two abnormal hemoglobin genes (HbSS). Carrier frequency of sickle cell disease varies significantly around the world, with high rates in areas with a high incidence of malaria.²²⁹ It is believed that the high frequency of the HbS variant is maintained in these populations by an increased resistance to malaria infection in heterozygous carriers. Sickle cell disease is the most common inherited blood disorder in the United States. About 8% of the African American population are carriers, and the homozygous form of sickle cell disease affects approximately 1 in every 396 African Americans.²³⁰ Less common forms of sickle cell disease include sickle cell–hemoglobin C disease and sickle cell– β -thalassemia.

When deoxygenated, the abnormal hemoglobin molecules form viscous polymers that aggregate with other hemoglobin molecules, distorting the red blood cells into an abnormal (sickle) shape. The tendency to form sickle cells is exacerbated by stressful conditions, such as illness, fever, cold temperature, and high altitude. The sickle shape results in less flexible red blood cells that obstruct the microcirculation, causing tissue hypoxia and infarction, which promote further sickling. Sickle-shaped red blood cells have a short life span of only 10 to 20 days, resulting in chronic anemia (i.e., sickle cell anemia). The complications of vascular occlusion are usually much more troublesome than the anemia, which is typically well tolerated.²³¹

The spleen usually is affected in patients with sickle cell disease. The most common splenic complications are autosplenectomy, splenic sequestration crisis, hypersplenism, massive splenic infarction, and splenic abscess.²³² In homozygous sickle cell disease, multiple infarcts during infancy usually result in a small, scarred, fibrotic spleen and complete loss of function, resulting in an end-stage spleen (i.e., autosplenectomy). By the age of 5 years, 94% of patients with homozygous sickle cell disease are asplenic.²³¹ In patients with heterozygous sickle cell disease, splenomegaly usually persists into adulthood.

On histologic examination, the end-stage spleen is replaced by fibrosis with calcium and hemosiderin deposits.⁴² On radiography, a small, heterogeneously dense spleen with punctate or amorphous calcifications can be seen. Patients with heterozygous sickle cell disease often present with splenomegaly and may demonstrate the sequelae of infarction.

The spleen is usually small, making it more difficult to visualize, with diffuse enhanced echogenicity demonstrated on sonography. Sometimes, hypoechoic foci are seen on ultrasound scans.²³³ CT usually shows a small and densely calcified

spleen (Fig. 105-22A).²³¹ The focal calcifications may be as small as 0.5 to 1.0 cm in diameter. MRI reveals diffuse, diminished signal intensity of the spleen relative to skeletal musculature on all sequences, representing calcifications and hemosiderin deposits.²³⁴ Diminished or no uptake of radiotracer, indicating loss of function, is seen on ^{99m}Tc -sulfur colloid scans of the liver and spleen (Fig. 105-22B).

Intrasplenic areas of preserved normal splenic tissue are sometimes present in an otherwise small and fibrotic spleen, and they should not be mistaken for an abscess or mass. These areas are hypoechoic relative to the echogenic spleen on ultrasound, are hypodense on CT, have the imaging characteristics of normal spleen on MRI, and demonstrate uptake of radiotracer on ^{99m}Tc -sulfur colloid imaging.²³⁵

Acute splenic sequestration is a life-threatening complication of sickle cell disease; it typically occurs in infants and children with homozygous sickle cell disease. It represents sudden trapping of a large amount of blood in the spleen, resulting in sudden splenic enlargement.²²⁹ A rapid fall in the hematocrit, hypovolemic shock, and death may occur within hours.²³⁶ On histologic examination, the splenic sinusoids are clogged with sickle erythrocytes, and there are areas of infarction, hemorrhage, and necrosis.

On imaging, the spleen is larger than expected. An apparently normal size may indicate an enlarged spleen because most patients have small spleens.²³¹ The spleen is heterogeneous with multiple hypoechoic areas on ultrasound. CT shows an enlarged spleen with heterogeneous enhancement and hypodense areas that may be interspersed with areas of higher attenuation. MRI of the spleen demonstrates areas of high signal intensity on the T1- and T2-weighted sequences, which is compatible with hemorrhage.²³⁶

The loss of splenic function is the pathophysiologic basis for increased susceptibility to aggressive, generalized infections, occurring in 10% of patients with homozygous sickle cell disease. Infections caused by encapsulated bacteria, including *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Salmonella*, are an important cause of morbidity and death.²³¹ A focal splenic abscess is a relatively uncommon complication. *Salmonella* was the most common causative organism identified in one series.²³⁷

SPLenic INVOLVEMENT IN PANCREATITIS

Epidemiology and Pathogenesis

Splenic involvement in pancreatitis occurs in 1% to 5% of patients and includes splenic vein thrombosis, infarction,

intrasplenic pseudocyst, subcapsular hematoma, splenic rupture, and hemorrhage from splenic artery pseudoaneurysm.^{238,239} Approximately 6% of patients with pancreatic pseudocysts have splenic parenchymal involvement.²⁴⁰

Complications usually result from direct extension of a pancreatic pseudocyst, caused by the digestive effects of pancreatic enzymes on splenic vessels or parenchyma, or from the liquefaction of splenic infarcts.²⁴¹ Most splenic parenchymal complications of pancreatitis regress spontaneously and can be managed conservatively.²⁴² However, potential complications, such as splenic rupture, infection, and hemorrhage, are life-threatening events.²⁴⁰

Radiologic Findings

CT is the most useful imaging technique for detection and follow-up of acute pancreatitis with or without splenic complications.²⁴³ Imaging typically reveals pancreatitis and its sequelae. Subcapsular splenic fluid collections or hematomas appear as lentiform collections that flatten or indent the splenic contour (Fig. 105-23). The appearance of the fluid collections depends on the amount of necrosis, infection, and hemorrhage.²⁴⁴ Evidence of fluid-fluid levels within a splenic pseudocyst favors the diagnosis of hemorrhage. Gas in a collection, although rare, confirms infection. Focal, wedge-shaped, or diffuse areas of decreased attenuation in the spleen are most likely to represent infarction. Portal vein thrombosis and pseudoaneurysms are typically detected with contrast-enhanced CT.

Percutaneous drainage of collections within or around the spleen may be considered to prevent splenic rupture and to treat infection. However, percutaneous drainage of splenic pancreatic pseudocysts has been associated with significant complications.²⁴⁰

GAUCHER'S DISEASE

Gaucher's disease is inherited in an autosomal recessive manner. The lipid storage disease is caused by a lack of the enzyme glucocerebrosidase.²⁴⁵ It is characterized by the deposition of

Figure 105-23 Pancreatic pseudocyst. Contrast-enhanced CT demonstrates an oval collection involving the splenic hilum in a patient with pancreatitis.

glucocerebroside in cells of the reticuloendothelial system. Three clinical subtypes have been described; type 1 is the most common. Gaucher's disease often is manifested in childhood with hepatosplenomegaly, pancytopenia, and skeletal disease, although striking clinical variability occurs in the severity of the disease. Glucosylceramide accumulation in the liver and spleen leads to pancytopenia and massive hepatosplenomegaly in most cases.

Histologic examination reveals a diffusely infiltrated spleen or focal clusters of glycolipid-laden macrophages (i.e., Gaucher cells). Fibrosis, infarction, and foci of extramedullary hematopoiesis may also be present.⁴²

Diagnostic imaging studies typically show massive splenomegaly. Nodular changes and infarcts are often present. The nodules are 0.5 to 7 cm in diameter.²⁴⁶ In a series of 46 patients with Gaucher's disease studied by MRI, 100% had hepatosplenomegaly, 33% had splenic infarcts, and 30% had splenic nodules.²⁴⁷

On sonographic evaluation, most patients with Gaucher's disease have multiple, discrete, hypoechoic lesions that correspond pathologically to focal, homogeneous clusters of Gaucher cells (Fig. 105-24A).^{246,247} Some patients have discrete, hyperechoic lesions that are composed of Gaucher cells and fibrosis or infarction.²⁴⁷

CT is useful in depicting splenomegaly and the hypodense nodules (Fig. 105-24B, C).²⁴⁶ On T1-weighted MRI, the signal intensity of the spleen tends to be lower than for normal spleens because of the accumulation of glucocerebroside.^{248,249} Nodules are isointense on T1-weighted imaging and variably hypointense or hyperintense on the T2-weighted images.²⁴⁹

HEMOSIDEROSIS

Hemosiderosis, or iron overload of the spleen, is usually caused by secondary hemochromatosis. It is most commonly seen in transfusion-dependent patients. After hemolysis of the transfused erythrocytes, excess iron is deposited in the reticuloendothelial system of the liver, spleen, and bone marrow.^{249,250} Abnormal iron accumulation in the reticuloendothelial system does not damage the parenchymal cells of the affected organ; it is usually of little clinical significance. There is often associated splenomegaly, depending on the underlying disease.²⁵¹

Splenic hemosiderosis should be differentiated from primary (idiopathic) hemochromatosis, an inherited autosomal recessive disorder. Primary hemochromatosis is characterized by inappropriately high iron absorption, resulting in progressive iron overload in the parenchymal cells.²⁵² Unless this condition is treated, it will lead to cellular and organ damage. The organs most commonly involved are the liver, causing cirrhosis and hepatic malignant neoplasms, and the heart and pancreas. The spleen usually is not affected or becomes involved only with advanced disease.

Ultrasound has a limited role because diffuse excess iron in the liver and spleen usually does not change the echogenicity. The increased iron deposition may cause diffuse increased attenuation of the liver and spleen on noncontrast CT examinations. However, CT is of limited value in the evaluation of increased iron deposition in the liver because of its poor sensitivity.²⁵²

MRI is the most helpful imaging technique to detect and to quantify iron storage disease.²⁵³ Iron causes increased magnetic susceptibility, which leads to increased T2* decay due

Figure 105-24 Gaucher's disease.

A. Splenomegaly and two irregular, nodular, hypoechoic lesions. **B.** Unenhanced CT shows splenomegaly but no focal abnormalities.

C. Contrast-enhanced CT shows ill-defined, hypodense lesions. These nodular areas correspond to focal homogeneous clusters of Gaucher cells determined at histopathologic examination. (Courtesy M. Maas, MD, Amsterdam, The Netherlands.)

to spin dephasing. The dephasing results in decreased signal intensity on MR images. In determining whether the signal intensity of the liver or spleen is abnormally low, muscle can be used as a control because skeletal muscle usually is spared. If the liver or spleen demonstrates signal intensity equal to or lower than that of skeletal muscle on the T2-weighted gradient-echo or T2-weighted spin-echo images (less sensitive), increased iron accumulation in the spleen can be suspected (Fig. 105-25).²⁵⁰⁻²⁵³

The dual gradient-echo technique is also helpful in the visualization of T2* effects. The splenic parenchymal signal intensity decreases on the image with the longer echo time because of continued decay of the transverse magnetization. Hepatic iron overload is discussed in Chapter 89.

THOROTRAST

Thorotrast is the trade name of a colloidal suspension of thorium dioxide and dextrin. It was used as a contrast agent from the 1920s through the mid-1950s. Thorium dioxide is radioactive, predominantly emitting alpha particles with a biologic half-life of 400 years.²⁵³ When it is used as an intravascular contrast agent, it is retained by the reticuloendothelial system and can be found in the liver, spleen, lymph nodes, and bone marrow years after it is administered.

Its former use has been reported in relation to its long-term effects. The alpha radiation causes a wide range of complications, primarily of the liver, and the major causes of mortality are cirrhosis and hepatobiliary and hematologic malignant neoplasms.^{254,255} Thorotrast increases the risk of

Figure 105-25 Hemosiderosis in a patient with transfusion-dependent thalassemia. There is marked decreased signal intensity of the liver and spleen compared with the skeletal muscles on axial, gradient recalled echo, T2-weighted MRI.

liver angiosarcomas, but this phenomenon has not been observed in the spleen, possibly because of the marked fibrosis and atrophy that typically develop.²⁵⁶

Splenic changes due to Thorotrast depend on the amount administered and exposure time. Thorotrast particles are phagocytosed by the reticuloendothelial cells, resulting in splenic pulp fibrosis and atrophy. Consequently, the spleen is small or has a normal size.

Abdominal radiographs show patchy, high-density, or punctate densities in the left upper quadrant. Sonography shows high-density areas in the liver, spleen, and abdominal lymph nodes. On CT, Thorotrast deposition in the spleen is demonstrated as homogeneous, high-density areas or punctate densities with or without atrophy. Similar high-attenuation changes are usually seen in the liver and abdominal lymph nodes. On MRI, the deposits may be seen as low signal intensity areas or signal voids on all sequences. In one study, the Thorotrast deposits were not detected on MRI.²⁵⁶

Primary Malignant Lesions

ANGIOSARCOMA

Epidemiology and Pathogenesis

Angiosarcoma, although rare, is the most common primary nonhematopoietic malignant tumor of the spleen (Table 105-3).²⁵⁷⁻²⁵⁹ The estimated annual incidence is 0.14 to 0.25 case per 1 million persons.²⁵⁸⁻²⁶⁰ Angiosarcomas are aggressive tumors, usually manifested with widespread metastatic disease, and they have a poor prognosis, with most patients dying within a year of diagnosis.²⁶⁰ The average age at presentation is older than 55 years, although angiosarcomas have been reported in all age groups, including children.²⁶¹ No apparent gender predilection is demonstrated.^{258,260} Unlike with angiosarcomas of the liver, correlation with exposure to toxins such as Thorotrast or vinyl chloride has not been documented. Rarely, angiosarcomas have been associated with previous chemotherapy for malignant lymphoma or radiotherapy for breast cancer.^{257,262}

Clinical Findings

The most common symptoms are abdominal pain (70%), fever (10%), fatigue, and weight loss.^{257,259,260} Splenomegaly is found in 70% of patients; spontaneous splenic rupture is relatively common at presentation and is reported in approximately 25% of patients.²⁵⁸⁻²⁶⁰ Anemia, thrombocytopenia, and coagulopathy are often encountered. Metastatic disease is common, usually widespread, and often rapidly progressive. The most common metastatic sites are liver, lungs, and bones.²⁵⁸

Special care should be taken before performing a percutaneous biopsy of a possible angiosarcoma of the spleen

or its metastases because of the high risk of massive hemorrhage.^{263,264}

Pathology

Macroscopic examination commonly reveals splenomegaly with hemorrhagic nodular changes.²⁵⁸ The cut specimens typically demonstrate multiple nodules of various sizes that are associated with hemorrhage, infarction, and necrosis.^{257,258,260} An unusual manifestation is a solitary mass.^{257,259} The microscopic appearance of splenic angiosarcomas is varied, and different growth patterns are observed, including sarcomatous solid, papillary, and epithelioid types.^{260,262} Hemorrhage and necrosis are frequently identified within the tumor.^{259,260,262} The main histologic features include irregular vascular channels lined by atypical endothelial cells. The well-differentiated areas appear as splenic sinus-like structures.²⁵⁷ In the more poorly differentiated areas, the tumors have a sarcomatous appearance. The solid areas may resemble an undifferentiated spindle cell sarcoma.^{258,260,262,265} With immunohistochemical techniques, it has been demonstrated that splenic angiosarcoma probably arises from the splenic sinus endothelial cells.²⁶⁶ On occasion, the histologic features suggest a mixed origin from blood capillaries and lymphatic endothelium.²⁶⁷

Radiologic Findings

The usual imaging appearance of splenic angiosarcoma is an aggressive splenic mass or masses associated with metastatic disease.²⁵⁷ Ultrasound examination often reveals splenomegaly and numerous, solid, ill-defined masses with a heterogeneous architecture (Figs. 105-26 and 105-27).²⁵⁹ Cystic areas are frequently encountered and probably represent necrosis, hemorrhage, or vascular lakes.^{257,259} Increased Doppler flow may be visualized in the solid areas and in the vascular lake areas (see Fig. 105-26B).

On CT, the most common presentation is an enlarged spleen containing multiple, ill-defined, hypervascular masses with heterogeneous contrast enhancement and areas of necrosis (see Figs. 105-26C, D and 105-27B).^{257,259} Intraspinal, subcapsular, or perisplenic hemorrhage is another frequently encountered manifestation.^{268,269} Calcifications are rare, but punctate and massive calcifications in a radial pattern have been reported.^{257,270}

MRI usually demonstrates splenomegaly with heterogeneous areas of increased and decreased signal intensity on the T1- and T2-weighted sequences, which is consistent with the presence of blood products and necrosis (see Fig. 105-27C, D).^{271,272} Low signal intensity lesions on MR images have been determined to represent siderotic nodules.²⁷³ Contrast-enhanced MRI demonstrates diffuse, heterogeneous, intense enhancement within the areas of the tumor, similar to the CT findings and corresponding to the pathologic changes (see Fig. 105-27E).^{257,259,268,271,272}

Angiography, occasionally performed for chemoembolization, demonstrates patchy accumulations of contrast material and irregular pooling of contrast material in the arterial and venous phases, which is consistent with vascular lakes (see Fig. 105-27F). Tumor vessels usually are not present.²⁷⁴ In our experience, early portal venous enhancement during angiography was observed, indicating arterial venous shunts.

Differential Diagnosis

The differential diagnosis includes benign lesions, such as hemangiomas, hemangioepitheliomas, abscesses, and littoral cell

TABLE 105-3 Malignant Tumors of the Spleen

+, Most common presentation; (+), uncommon presentation.

Figure 105-26 Angiosarcoma of liver and spleen. **A.** Ultrasound demonstrates a normal-sized, inhomogeneous spleen with a few “cystic” areas. **B.** Color flow is demonstrated in some of these areas, consistent with vascular lakes. **C** and **D.** CT after intravenous administration of contrast material in the arterial phase (**C**) and portal venous phase (**D**) shows many irregular areas of enhancement in the liver and spleen and areas of relatively low attenuation in the spleen. Autopsy revealed multiple angiosarcomas involving the spleen and liver. It was not possible to determine whether the spleen or the liver was the primary site.

angiomas, and malignant lesions, such as lymphomas, metastases, Kaposi’s sarcomas, and hemangioendotheliomas. All have similar imaging findings.^{257,259}

Secondary Malignant Lesions

LYMPHOMA

Epidemiology and Pathogenesis

Lymphoma is a malignant proliferation of lymphocytes arising in lymph nodes (nodal) or in lymphoid tissue of various organs, including the spleen (extranodal). Lymphoma is the fifth most common malignant neoplasm in the United States. Non-Hodgkin’s lymphoma (NHL) accounts for approximately 88%, and Hodgkin’s lymphoma (HL) accounts for 12%.^{275,276} Overall, NHL accounts for 5% of new cancers in men and 4% in women. NHL is responsible for approximately 5% of cancer deaths in the United States and is the leading cause of death from cancer in men between the ages of 20 and 39 years. The

World Health Organization classification recognizes more than 30 types of NHL, and there has been an increase in incidence and mortality rates of NHL worldwide during the past few decades.²⁷⁷

In general, the incidence of NHL increases with age. In contrast, a bimodal peak of presentation is seen for HL, with a peak between the ages of 20 and 29 years, a plateau between 30 and 55 years, and a second rise after 55 years. The incidence of lymphoma is higher among men than among women (1.5:1) for HL and NHL.²⁷⁵⁻²⁷⁷

There is an increased risk of lymphoma in immunocompromised patients, including patients with human immunodeficiency virus infection (HIV) and post-transplantation patients.²⁷⁸⁻²⁸⁰ Before the era of highly active antiretroviral therapy (HAART), the relative risk of AIDS-related lymphoma was more than 100.²⁸¹ In the HAART era, the risk of AIDS-related lymphoma remains increased relative to that for the general population, although it is lower than in the pre-HAART era.²⁸² AIDS-related lymphomas include NHL and HL, and they are usually highly aggressive. One of the diagnostic challenges

Figure 105-27 Angiosarcoma of the liver and spleen. A 62-year-old woman had a history of increasing upper abdominal pain on the left side, hepatosplenomegaly, pleural effusions, and coagulopathy. **A.** Ultrasound demonstrates a markedly enlarged spleen containing many ill-defined echogenic masses and hypoechoic areas. **B.** CT after intravenous administration of contrast material in the arterial phase shows a large, hypodense spleen with multiple areas of irregular enhancement and smaller similar lesions in the liver. **C.** T1-weighted image (FAME technique) at the same level reveals an enlarged spleen with ill-defined areas of decreased signal intensity relative to the surrounding spleen and areas of increased signal intensity (presumably hemorrhage). Multiple, small, hypointense lesions in the liver are also seen. **D.** Gadolinium-enhanced, T1-weighted MR image (FAME technique) at the corresponding level demonstrates an irregular central enhancement pattern and numerous enhancing lesions throughout the liver. **E.** The corresponding T2-weighted image (fast relaxation fast spin-echo = 3050/100 ms) demonstrates intrasplenic and intrahepatic masses with increased signal intensity. **F.** Pre-embolization angiogram during the early arterial phase shows splenomegaly, multiple hypervascular splenic masses, and vascular lakes.

of lymphoma in HIV-infected patients is that splenomegaly and lymphadenopathy are frequently also encountered in immunocompromised patients with nonmalignant conditions.²⁸³ The clinical and radiologic manifestations of AIDS-related lymphomas vary and may mimic Kaposi's sarcoma, mycobacterial

infections, fungal infections, and immune reconstitution inflammatory syndrome (Fig. 105-28).²⁸⁴⁻²⁸⁸

Splenic involvement is often observed in patients with malignant lymphomas, and lymphoma is the most common malignant disease that involves the spleen. Splenic involvement

Figure 105-28 Burkitt's lymphoma in a 32-year-old man with AIDS. **A.** The sagittal sonogram demonstrates marked splenomegaly and parenchymal calcification. **B.** Enhanced helical CT scan during the portal venous phase demonstrates marked splenomegaly with inhomogeneous splenic texture and a calcification. The CT appearance suggests diffuse lymphomatous infiltration.

usually occurs as part of a generalized systemic disease. Lymphoma confined to the spleen, called primary splenic lymphoma, is an uncommon manifestation that is encountered in less than 1% of patients; it usually is an NHL of B-cell origin.²⁸⁹⁻²⁹³

Routine staging for lymphoma includes laboratory investigations, bone marrow aspirate and biopsy, and cross-sectional imaging, including CT scans and often FDG PET imaging. Accurate staging is essential for patients with lymphoma in guiding their management and optimizing outcomes, and it includes evaluation of potential splenic involvement.²⁹⁴ Staging laparotomy with splenectomy, done before the routine availability of CT scanning, revealed splenic involvement in approximately 45% of patients with HL.²⁹⁵ Approximately 30% to 40% of patients with known NHL have splenic involvement at presentation.²⁹⁴

In general, splenic size correlates with the risk of lymphomatous involvement, and the presence of massive splenomegaly indicates a high probability of splenic involvement. However, marked splenomegaly may occur without lymphomatous involvement, and conversely, a normal size and appearance of the spleen do not exclude lymphomatous involvement.²⁹⁵⁻²⁹⁷

Definitive diagnosis of malignant lymphoma requires histopathologic analysis. Accurate diagnosis of the many subtypes of NHL usually requires an evaluation of the tissue's architecture. At minimum, this requires a core-needle biopsy and often requires an excisional biopsy. In HL, the malignant cells (i.e., Reed-Sternberg cells) are a minority of cells occurring in a background majority of polyclonal inflammatory cells, and tissue diagnosis is essential. With these caveats, in selected cases, percutaneous splenic biopsy can provide a diagnosis and possibly avoid splenectomy in cases with no other sites of involvement amenable to biopsy.^{264,298-301} Splenectomy may still be beneficial for patients with primary splenic lymphoma to provide a diagnosis and partial treatment.³⁰²

Clinical Findings

Lymphoma most commonly is manifested as a painless enlargement of one or more peripheral lymph nodes. Fever, night sweats, and weight loss often accompany the lymphadenopathy.^{289,290} Other nonspecific findings are abdominal pain,

abdominal masses, and splenomegaly. Primary splenic lymphoma may be manifested with left upper quadrant pain and splenomegaly.³⁰³ Lymphomatous involvement of the spleen is usually confined within the splenic capsule, but extracapsular extension and local invasion into adjacent organs can occur. Nontraumatic splenic rupture in lymphoma is a rare presentation.^{304,305} The combination of splenomegaly, focal splenic lesions, and associated lymphadenopathy should raise the suspicion of lymphoma (see Table 105-3). The prognosis depends on the histologic type and stage of the lymphoma.

Pathology

Classification of splenic involvement by lymphoma is based on the cell type and the architectural growth pattern. The white pulp is most commonly involved in primary and secondary lymphomas, followed by the marginal zone and the red pulp.³⁰⁶ Different macroscopic patterns of splenic involvement in lymphoma can be seen¹: homogeneous enlargement without masses²⁵⁸; miliary masses (<5 mm)²⁵⁹; multiple solid masses of various sizes²⁶⁰; and a large, solitary mass (>5 cm).^{290,306,307} HL is rarely extranodal in the immunocompetent patient, whereas extranodal involvement is common in NHLs. Large cell lymphomas usually are manifested as solitary or multiple tumor masses. The miliary nodules are more often caused by small cell lymphomas, such as follicular lymphomas of the small cleaved and mixed cell types and mantle cell lymphoma.^{262,265} Primary splenic lymphoma usually is manifested with a solid mass or masses, and it often represents NHL of B-cell origin.^{292,303} When HL involves the spleen, it commonly is manifested as solitary or multiple tumor masses (Fig. 105-29).^{262,308}

Radiologic Findings

Radiography. Radiography plays a limited role nowadays. When splenomegaly is present, it can be demonstrated on plain films of the upper abdomen with elevation of the left hemidiaphragm, deviation of the stomach and splenic flexure of the colon, and displacement of the left kidney.

Ultrasound. Although the specificity of ultrasound in detecting lymphomatous involvement of the spleen approaches 100%, the

Figure 105-29 Hodgkin's lymphoma in a 42-year-old man. **A.** The sagittal sonogram reveals an enlarged spleen containing multiple ill-defined, hypoechoic lesions. **B.** The CT scan of the upper abdomen demonstrates multiple low-density masses.

Figure 105-30 Malignant B-cell lymphoma in a 46-year-old man with subacute abdominal pain in the left upper abdomen. **A.** Focused sonography of the spleen demonstrates an anechoic peripheral area with some internal echoes. **B.** The enhanced helical CT scan during the portal venous phase shows a hypodense peripheral lesion and splenomegaly. Similar lesions were demonstrated in the liver (not shown).

sensitivity is low (63%). This may be explained by a poor sensitivity in detecting diffuse involvement.^{309,310} Sonography is possibly more sensitive than CT, especially in detecting inhomogeneities or small, nodular infiltrates.^{309,310}

Four different sonographic patterns are described in patients with lymphomatous involvement of the spleen corresponding with the pathologic findings²⁵⁷: diffuse involvement (37%)²⁵⁸, focal, small nodular lesions (39%)²⁵⁹; focal, large nodular lesions (23%)²⁶⁰; and bulky, solid mass lesions (2%).³¹¹ Diffuse involvement usually is manifested as splenomegaly with a normal echotexture. Focal lesions are hypoechoic and lack acoustic enhancement (see Fig. 105-29A).³¹¹⁻³¹³ A diffuse, small, nodular

pattern is predominantly visualized in cases of low-grade NHL and in HL.³¹¹ On occasion, after central necrosis occurs with subsequent liquefaction, lesions may be manifested as anechoic masses with or without septations, mimicking cystic lesions of the spleen or even abscesses (Fig. 105-30A).³¹⁴⁻³¹⁷

Computed Tomography. CT is the established radiologic technique for staging of lymphomas.^{318,319} New-generation multidetector CT scanners allow rapid imaging of the entire body during a single breath hold with a high spatial resolution. Both nodal and extranodal involvement can be detected with CT. CT is used to evaluate tumor location and volume

Figure 105-31 B-cell non-Hodgkin's lymphoma. A 74-year-old woman had a 2-month history of increasing general fatigue and low-grade fever. **A.** The enhanced CT scan during the portal venous phase shows an ill-defined, solitary, hypodense lesion in the inferior portion of the spleen. The spleen was moderately enlarged, and extensive para-aortic, paracaval, and abdominal lymphadenopathy is also visible. **B.** The enhanced CT scan of the upper abdomen 3 months after chemotherapy demonstrates marked improvement of the lymphadenopathy and decreased size of the splenic lesion.

and to monitor response to therapy (Fig. 105-31).^{320,321} CT also is helpful in planning surgical or percutaneous biopsy procedures and for planning radiotherapy. The most important limitation of CT is the inability to identify the involvement of disease in normal-sized lymph nodes and the relatively poor sensitivity in the detection of splenic, brain, and bone marrow infiltration.^{322,323} Furthermore, CT is not able to evaluate disease activity in residual tissue after treatment.³²⁴

The combined use of FDG PET imaging and CT (hybrid PET/CT) offers the advantages of excellent anatomic resolution of CT and the biologic characterization provided by FDG PET. The combination improves overall accuracy in staging of the disease.^{325,326}

Splenomegaly with hypodense lesions may be observed on the noncontrast CT scan. However, intravenous administration of contrast material is usually required to demonstrate focal splenic involvement (Fig. 105-32). The physician should be careful when evaluating the images in the arterial phase because variable contrast enhancement of the normal spleen resulting from differential flow through the vascular sinuses and cords of red and white pulp is common. In almost all patients, this heterogeneity resolves after 60 to 70 seconds.³²⁷⁻³²⁹

Different CT appearances of splenic lymphoma have been described²⁵⁷: normal size and appearance²⁵⁸; enlarged with no focal defects²⁵⁹; diffuse, miliary, hypodense lesions (Fig. 105-33)²⁶⁰; multiple, focal masses of various sizes (see Fig. 107-29B)²⁶¹; and a solitary, large mass (>5 cm; Fig. 105-34).³⁰³ The spleen may be bulky in patients with primary or secondary splenic lymphoma. The focal splenic masses caused by lymphoma usually demonstrate minimal enhancement and have a hypodense appearance compared with the surrounding spleen (see Fig. 105-32).

Rim-enhancing lesions with central necrosis may mimic splenic abscesses. Wedge-shaped, hypodense areas in patients with lymphoma and leukemia are sometimes observed and probably reflect secondary splenic infarction.

Large masses demonstrating capsular involvement and perisplenic infiltration into adjacent organs may be observed.

Splenic calcifications after treatment of lymphoma are occasionally seen; calcifications before treatment of splenic lymphoma are rare (Fig. 105-35; see also Fig. 105-28).^{303,330}

Magnetic Resonance Imaging. MRI is superior to CT in assessing lymphomatous involvement of extranodal disease in the brain, spinal cord, and bone marrow.³³¹ However, MRI has the same limitations as CT in detecting lymphomatous involvement in normal-sized lymph nodes and in residual tumor masses after therapy. The main disadvantages of MRI compared with CT include higher costs, longer scan time, and respiratory artifacts. For staging of abdominal lymphomas, MRI with a T2-weighted, turbo spin-echo sequence demonstrated results similar to those of spiral CT in detecting lymphadenopathy and demonstrating focal abdominal organ lesions.³³² In an older study, MRI and ultrasound were better than CT in revealing HL infiltrates in the spleen. However, most lymphomatous involvement of the spleen by NHL was not revealed with any of these modalities, except when the size of the spleen was considered.³³³ With the development of new and faster imaging techniques and the addition of diffusion-weighted imaging, excellent results have been reported in staging of lymphoma with MRI.³³⁴

Lymphoma involving the spleen usually has T1 and T2 imaging characteristics similar to the normal splenic parenchyma, making adequate staging challenging. If focal lesions are identified, they tend to have variable signal intensity on the T1- and T2-weighted images. Dynamic gadolinium-enhanced sequences usually are required for better evaluation of splenic lymphomatous involvement.³³⁵ T1-weighted, spoiled gradient-echo images immediately after administration of gadolinium and with a delay of approximately 20 seconds provide the best sensitivity.^{336,337} Diffuse involvement may be demonstrated as splenomegaly with irregularly enhancing regions of high and low signal intensity. Focal lesions can be demonstrated in the normal, enhancing spleen. Multifocal disease can be seen as many focal, hypointense lesions relative to the surrounding spleen. Nodular lesions may have low signal intensity on the T2-weighted images compared with the normal spleen, and this feature can be used to differentiate lymphoma from metastatic

Figure 105-32 Primary lymphoma of the spleen in a 60-year-old woman. The nonenhanced helical CT scan (**A**), CT scan during the portal venous phase (**B**), and CT scan 7 minutes after intravenous injection of contrast material (**C**) demonstrate splenomegaly and an approximately 8-cm-diameter mass of decreased attenuation. Splenectomy revealed a large B-cell lymphoma.

solid organ tumors because metastases rarely have low signal intensity on T2-weighted images (Fig. 105-36).^{337,338}

Secondary cystic, necrotic, or hemorrhagic changes may be helpful in detecting splenic involvement on MRI.³³⁹ The use of MR contrast agents, such as reticuloendothelial system–specific superparamagnetic iron oxide, appeared to be a promising approach for the evaluation of focal splenic lesions, as demonstrated in a few small series.^{340,341} There is normal uptake of the superparamagnetic particles in the reticuloendothelial system, causing decreased signal intensity on T2-weighted images. There is no uptake of the superparamagnetic particles in the malignant cells, and these areas do not change in signal intensity, making them more conspicuous.^{337,342} However, use of these specific contrast materials in general radiologic practice remains limited, and not much has been published recently.

Nuclear Imaging. FDG PET is a functional imaging technique based on glucose metabolism in tissue. In most lymphomas, the involved tissue is hypermetabolic, with resultant increased intracellular glucose accumulation. FDG PET demonstrates increased uptake of the radiopharmaceutical in affected tissue (Fig. 105-37).

FDG PET has had higher sensitivity and specificity than CT and all other imaging modalities in many comparative series. In several circumstances, FDG PET may change the primary staging, planning, and monitoring of therapy for lymphoma patients.³⁴³ Whether FDG PET can change clinical management and consequently affect survival (outcomes) is

a subject of ongoing investigation.^{344,345} FDG PET can be performed at the same time as CT imaging in the form of hybrid or fusion PET/CT. PET/CT already has become the preferred initial staging tool for patients with lymphoma at some institutions.³²²

Limitations of FDG PET are its lack of availability, high operating expenses, and false-positive and false-negative results for patients with lymphoma. For example, false-positive results may occur for metabolizing tissue such as muscle or inflammatory tissue, and indolent (low-grade) NHL may fail to take up FDG, yielding false-negative results. The role of FDG PET imaging in certain types of lymphoma, such as T-cell NHL and highly aggressive NHL, is still uncertain. ^{99m}Tc-sulfur colloid and ⁶⁷Ga-citrate forms of scintigraphy have low sensitivity, specificity, and accuracy in detecting splenic lymphoma.³⁴⁶ Since the introduction of FDG PET, these two imaging modalities have played a limited role in the evaluation of splenic lymphoma.³⁴⁷

LEUKEMIA AND MYELOPROLIFERATIVE DISORDERS

The spleen often is involved in myeloproliferative disorders and in acute and chronic leukemias.²⁶⁵ Unlike lymphoma, these disorders mainly affect the red pulp, although the white pulp eventually may be infiltrated.^{262,265} Splenomegaly is often encountered, but the frequency and severity depend on the type and duration of the disease. Diffuse involvement and focal, solid lesions

Figure 105-33 Mantle cell lymphoma in a 70-year-old woman. Coronal, multiplanar reformat reconstruction CT scan during the late venous phase demonstrates massive splenomegaly displacing the surrounding organs. The spleen has an inhomogeneous, miliary appearance.

Figure 105-34 Diffuse small cell lymphoma. CT demonstrates a hypodense mass with capsular invasion. There is lymphadenopathy surrounding the celiac axis and splenic artery.

(solitary or multiple) have been described.³⁴⁸ Unlike lymphoma, the focal lesions are often hyperechoic on ultrasound.³⁴⁹ Extramedullary hematopoiesis may cause echogenic lesions in these patients.³⁴⁸ Splenic rupture is an uncommon manifestation of leukemic disorders and may be caused by infiltration of the splenic capsule and trabecular framework or by infarction (Fig.

Figure 105-35 Punctate calcifications throughout the spleen 5 years after successful treatment of non-Hodgkin's lymphoma. Calcified lymph nodes (not shown) were also demonstrated in other locations. (Courtesy M. de Jonge, Amsterdam, The Netherlands.)

105-38).^{350,351} Fine-needle biopsy can be performed for definitive diagnosis.²⁹⁸⁻³⁰¹

METASTATIC DISEASE

Epidemiology and Pathogenesis

Splenic involvement by metastases is relatively uncommon and occurs with a frequency of 0.6% to 7.1% in autopsy series.^{352,353} Different types of splenic involvement can be encountered; patients most commonly present with solitary or multiple nodules. On occasion, a miliary pattern, diffuse infiltration of the parenchyma, serosal implants, or direct tumor invasion from adjacent organs is encountered.^{262,352} Tumors that most commonly metastasize to the spleen are melanoma (34%), breast (12%), ovary (12%), colon (10%), and lung (9%).³⁵³ In a study of an Asian population, the lung was the most common primary tumor site (21%), followed by the stomach (16%), pancreas (12%), liver (9%), and colon (9%).³⁵² Kaposi's sarcoma can involve the spleen, usually in AIDS patients with disseminated Kaposi's sarcoma. Isolated metastases to the spleen are very rare, with approximately 40 cases reported in the literature.^{352,354,355}

Several theories have been proposed for the relatively uncommon occurrence of splenic metastases. The absence of afferent lymphatic vessels in the splenic parenchyma is the most likely explanation.^{262,265,353} Hematogenous spread through the splenic artery is considered the most probable origin of metastases, and the frequency of splenic metastases is comparable to that of the kidney.³⁵³ Much less common pathways are metastases through the splenic vein in patients with portal hypertension and retrograde lymphatic spread from nodes in the splenic hilum.^{353,356}

Implants on the serosal surface of the spleen are seen in patients with peritoneal carcinomatosis from ovarian cancer, gastrointestinal adenocarcinoma, and pancreatic cancer. The implants cause indentation and scalloping of the surface of the spleen with solid and cystic components, and these features are typically well demonstrated by CT (Fig. 105-39).

Figure 105-36 Lymphoma. Axial (A) and coronal (B) half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR images demonstrate low signal intensity masses in the spleen of a 32-year-old pregnant woman with a low-grade lymphoma. (Courtesy D. Vanbeckevoort, MD, Leuven, Belgium.)

Figure 105-37 Large B-cell lymphoma. Left, PET maximum intensity projection image demonstrates a large peripheral area of increased fluorine-18-deoxyglucose (FDG) uptake with a central hypometabolic region involving the spleen. Right, Corresponding CT image after intravenous administration of contrast material demonstrates a large, hypodense, necrotic mass involving the central spleen. (Courtesy R. Attariwala, MD, PhD, Vancouver, Canada.)

Figure 105-38 Spontaneous splenic rupture. In a 69-year-old man with acute lymphoblastic leukemia, the enhanced helical CT scan demonstrates splenomegaly and multiple hypoechoic areas, subcapsular and pericapsular dense fluid, and free fluid around the liver. Laparotomy and splenectomy confirmed a ruptured subcapsular hematoma and diffuse leukemic involvement of the spleen.

Figure 105-39 Splenic metastasis from colon cancer. In a 56-year-old woman, enhanced helical CT scan shows large splenic lesions with capsular invasion and subcapsular and intrahepatic metastases. CT also demonstrated diffuse tumor infiltration of the abdomen, peritoneal and omental nodules, and subcapsular and intrahepatic metastases. Laparotomy confirmed these findings and showed a cecal adenocarcinoma. (Courtesy C. Keogh, MD, Vancouver, Canada.)

Psammomatous or dense calcifications can be seen in cases of metastatic mucinous adenocarcinoma. Pseudomyxoma peritonei, characterized by extensive spread of a mucin-secreting neoplasm along the peritoneal surfaces, often also involves the spleen.

Direct tumor invasion of the spleen is uncommon. Spread may occur from adjacent organs, such as lymph nodes at the hilum, stomach, colon, pancreatic tail, or left kidney, or from tumors in the retroperitoneum (Figs. 105-40 and 105-41).³⁵⁷

Figure 105-40 Direct invasion of the spleen by a pancreatic adenocarcinoma. In a 63-year-old man, the enhanced CT scan of the upper abdomen shows a partially solid and partially cystic mass involving the tail of the pancreas that is invading the spleen. Percutaneous biopsy from the pancreatic tail mass revealed a pancreatic adenocarcinoma.

Figure 105-41 Direct invasion of the spleen by a pancreatic mucinous cystadenocarcinoma. In a 52-year-old woman, the enhanced CT scan of the upper abdomen demonstrates a septate cystic mass with some coarse calcifications involving the tail of the pancreas (not shown) that is invading and displacing the splenic hilum. A few small, hypodense lesions in the spleen are consistent with metastatic disease.

Clinical Findings

Splenic metastases usually are seen in patients with advanced disease and widespread involvement of other organs. Solitary splenic metastasis in the absence of other metastases is rare, and splenectomy may be beneficial in these isolated cases.^{355,358,359}

Most splenic metastases do not cause symptoms and are found during routine staging. Splenomegaly is rarely encountered.³⁵⁴

Few patients are symptomatic, and they may present with an abdominal mass, left upper quadrant discomfort due to splenomegaly, and acute pain due to splenic infarcts caused by tumor emboli. More often, patients present with symptoms of disseminated metastatic disease, such as anorexia and cachexia. When there is diffuse parenchymal involvement, the patient may present with hematologic abnormalities and thrombocytopenia. Splenic rupture caused by nonhematologic malignant neoplasms is rare, with approximately 22 cases reported in the literature.³⁶⁰

Pathology

Approximately 80% of splenic metastases can be identified macroscopically.^{352,353} Different types of splenic involvement can be encountered, including solitary metastases, multiple metastases, metastases to the splenic capsule, and diffuse infiltration of the splenic red pulp.^{262,265,352} Most metastatic tumors are manifested as solitary or multiple nodules, and diffuse infiltration is a rare phenomenon.

Radiologic Findings

Ultrasound. The sonographic appearance of splenic metastases varies. Focal lesions can be hypoechoic, mixed, or cystic, or they can have a target or halo appearance (i.e., echogenic lesion with hypoechoic rim).³⁶¹ Approximately 50% of focal splenic metastases are hypoechoic; the larger lesions tend to be more complex. Hyperechoic metastases are rare but can be seen in patients with melanoma, nasopharyngeal carcinoma, and colon and gastric cancers (Fig. 105-42).^{362,363} No correlation between the sonographic features of the metastases and the type of the primary tumor has been demonstrated.³⁶¹

Computed Tomography. Splenic metastases are typically ill-defined, hypodense, rounded lesions (Fig. 105-43). Noncontrast scans are usually not helpful in depicting splenic metastases. In most cases, tumor conspicuity is best in the portal venous phase 60 to 70 seconds after intravenous administration of contrast material because of the normally inhomogeneous early enhancement pattern of the spleen. Splenic metastases occasionally may appear cystic or necrotic.³¹⁷ Cystic metastases may be unilocular or multilocular, and the septations and the periphery may show enhancement.^{317,327} Differentiation of cystic metastases from true splenic cysts may prove difficult.

Splenic metastases with calcifications are rare. Calcifications may be seen in metastases from a mucinous adenocarcinoma (Fig. 105-44).³⁶⁴

Magnetic Resonance Imaging. Splenic metastases are often isointense or slightly hypointense on T1-weighted images and are usually slightly hyperintense on T2-weighted images. Metastases are rarely hypointense on T2-weighted images, and this fact can be used to differentiate splenic metastases from lymphoma.^{337,338} Melanoma metastases may demonstrate

Figure 105-42 Hyperechoic splenic metastasis from melanoma. Ultrasound demonstrates multiple hyperechoic masses throughout the spleen. Multiple similar lesions were present throughout the liver (not shown).

Figure 105-43 Splenic metastasis from lung cancer. The enhanced CT scan of the upper abdomen during the portal venous phase reveals an ill-defined, hypodense mass in the spleen 6 months after resection of a lung cancer (i.e., confirmed squamous cell cancer).

high signal intensity on the T1-weighted images because of the T1 shortening effect of melanin.³⁶⁵ MRI can easily detect necrotic or cystic components. The degree and characteristics of enhancement depend on the nature and type of the primary neoplasm.³³⁸ Metastases are usually hypointense on

Figure 105-44 Splenic metastasis and peritoneal carcinomatosis from ovarian cancer. Noncontrast CT of the upper abdomen reveals an ill-defined mass containing a few small calcifications invading the hilum of the spleen.

T1-weighted images after the administration of gadolinium. Early (20 seconds) dynamic gadolinium-enhanced imaging is essential because the metastases typically become isointense with the splenic parenchyma after approximately 30 seconds.³³⁷ After treatment, metastases usually demonstrate decreased enhancement and diminished signal intensity on T2-weighted images. The use of specific contrast agents (e.g., superparamagnetic iron oxide) increases lesion conspicuity and decreases the threshold size for lesion detection.^{342,366} However, the use of these agents remains limited in a general radiologic practice.

Nuclear Scintigraphy. FDG PET is becoming the imaging modality of choice for the diagnosis and follow-up of malignant neoplasms, and growing evidence supports its use.^{367,368} The strength of PET imaging is in detecting both nodal and extra-nodal metastases. FDG PET demonstrates focal increased uptake of the radiopharmaceutical in affected locations (Fig. 105-45). The role and accuracy of FDG PET in diagnosis and staging of different malignant neoplasms are being studied, but the accuracy in detection of metastases to the spleen has not been evaluated.³⁶⁹ The combined use of FDG PET imaging and multidetector CT (PET/CT) produces an integrated examination for functional and anatomic imaging.³⁷⁰⁻³⁷⁴ PET/MR also combines functional imaging with the superb contrast resolution of MR.³⁷⁵

Since the introduction of FDG PET, there is no longer a clinical use for ^{99m}Tc-sulfur colloid and ⁶⁷Ga imaging to detect splenic metastases. ^{99m}Tc-sulfur colloid scintigraphy has low sensitivity and specificity for screening of splenic metastases. When abnormalities are detected on these scans, focal defects are demonstrated in the spleen, but the findings are nonspecific. ⁶⁷Ga imaging of splenic metastases is unreliable and of limited clinical use in detecting metastases.

Figure 105-45 Splenic metastases from a malignant melanoma as imaged by PET/CT. **A.** The nonenhanced CT scan of the upper abdomen demonstrates a hypodense area centrally in the spleen. **B.** The axial PET image demonstrates two areas of increased ^{18}F -fluorodeoxyglucose (FDG) activity. **C.** The fused PET/CT image demonstrates the two FDG-avid lesions localized anatomically within the spleen. **D.** The maximum intensity projection image demonstrates the large and small (medial) splenic lesions and another lesion inferior to the largest lesion, which projects lateral to the kidney. CHAPTER OUTLINE

Splenic Trauma

Epidemiology

Clinical Findings

Pathophysiology

Radiologic Findings

Complications of Splenic Injury

Treatment and Outcome

Splenic Surgery

Splenic Trauma

The spleen is the most commonly injured organ in blunt abdominal trauma.^{1,2} It receives 5% of the cardiac output, accounts for 25% of the total reticuloendothelial cell mass, and plays a major role in clearing the plasma antigens.³ Recognition of this fundamental role in the immune response during the last century has led to greater efforts to preserve the spleen after injury. Nonoperative management is now widely accepted in carefully selected, hemodynamically stable patients. Development of sophisticated and accurate diagnostic imaging techniques, such as multislice computed tomography (CT), has been a major driving force behind these changes. The accurate diagnosis of splenic injury has therefore assumed an increasingly important role in the evaluation of the traumatized patient. It is very difficult to exclude solid organ injury in patients with blunt abdominal trauma without CT.⁴ CT greatly facilitates selection of patients who are treated nonoperatively by allowing accurate identification and characterization of splenic injuries as well as of other associated injuries.^{5,6} Both CT and ultrasound are important in the immediate follow-up of these patients, although ultrasound may fail to demonstrate injury in the absence of hemoperitoneum.⁷⁻¹⁰

EPIDEMIOLOGY

The spleen can be injured by various mechanisms, including blunt abdominal trauma, penetrating injuries, and iatrogenic and intraoperative accidents. Splenic injury accounts for approximately 25% of all solid abdominal organ injuries.¹¹ Motor vehicle accidents and motor sports produce most splenic injuries, followed by direct blows and falls.¹¹ Associated injuries of the central nervous system, liver, kidney, and hollow viscera occur in 10% to 40% of blunt splenic injuries, and these may alter therapeutic options.¹²

Penetrating trauma of the chest or abdomen can also result in splenic injury. Whereas penetrating trauma may involve the spleen, the spleen is less frequently injured compared with the small and large intestine. Up to 40% of all splenectomies are performed for iatrogenic injury. The risk of splenic injury is

highest during left hemicolectomy (1%-8%), open antireflux procedures (3%-20%), left nephrectomy (4%-13%), and exposure and reconstruction of the proximal abdominal aorta and its branches (21%-60%); most iatrogenic injuries result from excessive retraction and disruption of ligamentous attachments.¹³ Penetrating iatrogenic splenic injuries during interventional procedures involving the left kidney can occur because of the variable relationship of the spleen and the left kidney.¹⁴⁻¹⁶ Splenic injury is an uncommon complication of colonoscopy that may be unsuspected clinically but evident on CT scans.¹⁷⁻¹⁹

CLINICAL FINDINGS

The clinical diagnosis of splenic injury after blunt abdominal trauma can be difficult. As many as 40% of patients with significant intra-abdominal trauma may have no apparent signs or symptoms on their initial presentation to the emergency department.^{1,20-22} In the setting of blunt abdominal trauma, non-CT criteria can identify only 12% of patients without intra-abdominal injuries and 22% of patients without major injuries.⁴ Laboratory analysis in combination with physical examination findings can contribute significantly to the identification of intra-abdominal injuries after blunt trauma.²³ However, diagnostic clues can be masked in the presence of intracranial or spinal injury, shock, or intoxication.^{22,24-26} One study has shown clinically significant findings on CT in 19% of trauma patients with no obvious signs of chest or abdominal injury.²⁷

The patient's complaints may include left upper quadrant tenderness or referred left shoulder pain (Kehr's sign), which may be elicited best by placing patients in the Trendelenburg position. Rib fractures are found in 7% to 10% of patients with multiple trauma.^{28,29} Hypotension and overt shock occur in approximately 30% to 40% of patients with splenic injuries, although this number continues to decline with advances in field resuscitation and transport. Signs of persistent intraperitoneal hemorrhage or hemodynamic instability are clear indications for surgery. Many surgeons continue to advocate the use of diagnostic peritoneal lavage (DPL) for the evaluation of splenic injuries, especially in the unstable or multiply injured patient. The relative value of DPL compared with CT continues to be debated; however, a major limitation of DPL is its lack of specificity as the injured organ may be difficult to identify and the grade of injury cannot be determined.³⁰⁻³² Care should also be exercised when DPL is performed before abdominal CT as the lavage fluid may reduce attenuation of hemoperitoneum because of dilution.

PATHOPHYSIOLOGY

The spleen is particularly susceptible to injury after blunt trauma because of its complex ligamentous attachments and

Figure 106-1 Splenic arterial anatomy. The arterial anatomy of the spleen follows a predictable segmental anatomy. The arterial branch vessels enter the spleen perpendicular to its long axis, as shown in this maximum intensity projection image from a CT angiogram.

spongy parenchymal consistency. The spleen is firmly attached to the retroperitoneum by the lienorenal and phrenocolical ligaments. It is also attached to the mobile colon and stomach by the gastrosplenic and colosplenic ligaments.³³ The spleen is divided into four or six segments by arterial supply, whereas the venous system is highly anastomotic and does not follow a predictable segmental anatomy. The arterial branch vessels enter the spleen perpendicular to the long axis, allowing segmental resection (Fig. 106-1). The spleen is enclosed within a thin capsule derived from the peritoneum. In pediatric patients, the splenic capsule is relatively thicker and contains more elastic and contractile elements.³⁴

The spleen can be injured by sudden compression or contrecoup mechanisms during rapid deceleration. In deceleration injuries, the mobility of the stomach and the transverse colon is transferred to the spleen, which results in ligamentous-capsular avulsions or vascular injury to the pedicle or short gastric vessels. Blunt compression can occur from a direct blow or transmitted shock wave and usually results in parenchymal injuries and venous bleeding along segmental anatomic lines. With greater energy transfer, blunt injury does not respect segmental anatomy, and stellate fractures occur with extensive arterial and venous bleeding.³³ Injuries that result in parenchymal hematomas with an intact capsule are less common than was originally believed but may account for the 1% to 2% incidence of delayed splenic rupture.³⁵

The sequelae of penetrating splenic injury depend on the wounding instrument and its trajectory. In contrast to blunt trauma, penetrating trauma does not respect segmental anatomy and tends to have more vascular disruption. Penetrating trauma also has a higher incidence of associated organ injury, including

the gut, which typically necessitates exploration. An abnormal spleen is prone to injury by trivial trauma.

The enlarged spleen is more prone to blunt injury and is exposed beneath the rib cage. Splenomegaly can result from a variety of disease states, including portal hypertension, blood dyscrasias, infection, and lymphoproliferative disorders.

RADIOLOGIC FINDINGS

Imaging of patients with abdominal trauma is secondary to initial resuscitation efforts and clinical evaluation. Although plain films are part of most standard trauma protocols, the appropriateness of cross-sectional imaging depends on the clinical situation. Hemodynamically unstable patients or individuals with critical nonabdominal injuries that require immediate attention are not suitable candidates for CT and are typically evaluated by DPL or are explored immediately.^{1,36} However, in hemodynamically stable patients, imaging can play an invaluable role in detecting and staging splenic injury.³⁷⁻³⁹ Imaging can also be useful in the follow-up and postoperative evaluation of these patients.

Computed Tomography

CT has become the “gold standard” for the diagnosis of splenic injuries after trauma.⁴⁰⁻⁴³ CT has an accuracy exceeding 95% in the detection of splenic injuries. However, these impressive results can be obtained only by use of meticulous CT technique. Streak artifacts from the patient’s arms, external wires and hardware, nasogastric tubes, and gastric distention or gastric air-fluid levels should be avoided or minimized. Contrast-enhanced multislice CT is the current method of choice for evaluation of trauma patients with suspected abdominal injury in most institutions. Multislice CT scanning with bolus technique is preferred to optimize injury detection and to minimize delay within the department.^{39,44-46} Multislice scanners with fast tube rotation minimize scanning time and motion artifact.^{39,44,46}

Assessment of splenic injury should include evaluation for hematoma, extent of laceration, active extravasation of contrast material, and associated vascular injuries.⁴⁷ Splenic hematomas are hyperdense relative to the splenic parenchyma on unenhanced CT and generally hypodense on contrast-enhanced CT. Splenic hematomas may be intraparenchymal, subcapsular, or perisplenic. Intrasplenic hematomas (Fig. 106-2) typically appear as hypodense areas within the splenic parenchyma after administration of contrast medium.^{26,37,38,48} These intrasplenic hematomas may be nearly isodense in some cases, particularly after inadequate administration of contrast material.^{26,49,50}

Splenic lacerations on CT appear as linear, low-attenuation foci that may not extend completely across the spleen (Fig. 106-3). Lacerations may be single, multiple, or stellate (Fig. 106-4). Splenic fractures (Fig. 106-5) are defined as lacerations that extend completely across the splenic parenchyma and commonly involve the splenic hilum. Intraparenchymal lacerations become smaller and less dense with smoother margins over time. This healing may take weeks, and follow-up CT, particularly in the setting of an uncomplicated clinical course, is not helpful and does not affect management.^{7,51-53} Follow-up imaging after hospital discharge is not advocated by many centers.⁵²⁻⁵⁴

Subcapsular hematomas follow the splenic contour and compress the parenchyma. Subcapsular hematomas (Fig. 106-6) typically appear as crescentic fluid collections along the lateral

Figure 106-2 Intrasplenic hematoma. Hematoma is demonstrated as a low-density collection of blood (arrows), which can vary in attenuation from hypodense to isodense relative to the spleen.

Figure 106-3 Splenic laceration. Laceration (arrow) extends to the splenic hilum and is associated with traumatic pseudoaneurysm with dissection. Notice the small perisplenic hematoma.

Figure 106-4 Complex splenic laceration. Linear foci of low attenuation (long arrows) are consistent with lacerations. There is segmental ischemia in the anterior aspect of the spleen. A small perisplenic hematoma (arrowhead) and a large hepatic laceration (short arrows) are identified.

Figure 106-5 Splenic fracture. The lacerations traverse the splenic parenchyma (arrows). A small perisplenic hematoma is identified (arrowhead).

aspect of the spleen, which may be difficult to distinguish from perisplenic fluid (Fig. 106-7). These hematomas become less dense over time and may mimic free intraperitoneal fluid. However, mass effect on the splenic parenchyma and its location between the enhancing capsule and the parenchyma distinguishes it from free fluid. Subcapsular hematomas usually resolve within 4 to 6 weeks. These hematomas are not associated with delayed splenic rupture and are not an indication for splenorrhaphy.⁵⁵

Severe disruption of the splenic parenchyma results in a “shattered” spleen (Fig. 106-8). Vascular pedicle injuries usually result in significant hemorrhage and cardiovascular instability and are usually not referred for CT evaluation. These patients do have a characteristic CT appearance with nonenhancement of the caudal portion of the spleen and preservation of upper pole perfusion through the short gastric arteries.⁴⁷ Active

hemorrhage appears as areas of irregular collection of contrast material that can be distinguished from adjacent clot by its density (Fig. 106-9).^{37,55} Extravasated contrast material has a higher mean attenuation than hematoma (132 HU vs 51 HU).⁵⁶ In general, contrast material extravasation has a higher likelihood of splenic hemorrhage at laparotomy.^{37,56} Laparotomy in these patients may be avoided by prophylactic embolization of the proximal main splenic artery.^{43,57,58}

Splenic injuries may be subtle, and parenchymal or capsular lesions may not be directly visualized. The presence of perisplenic high-attenuation fluid or clot, the so-called sentinel clot (Fig. 106-10), is a useful indicator of splenic injury.^{2,48} In one series, 20% of patients with surgically proven splenic injury demonstrated perisplenic clot as the principal finding. Another subtle sign of limited splenic injury is thickening of the anterior renal fascia and the left lateroconal fascia, presumably from

Figure 106-6 Subcapsular hematoma. The low-attenuation fluid collection is located along the lateral surface of the spleen and causes straightening of the lateral margin. The subcapsular hematoma follows the contour of the spleen. Coronal reformations can be particularly helpful for the assessment of the location of intra-abdominal free fluid in the setting of trauma.

Figure 106-8 Shattered spleen. Severe splenic injury after blunt trauma resulted in fragmentation of the spleen (S). Several islands of enhancement are identified (arrowhead). These focal areas of enhancement may represent pseudoaneurysm formation, which can be a predictor of the need for endovascular or surgical intervention. Splenectomy was required in this patient. Associated injuries of the left kidney and right adrenal gland (arrow) also are identified. Streak artifact from the patient's arms along the abdomen degrades image quality.

Figure 106-7 Larger subcapsular hematoma. Distinction between subcapsular and perisplenic fluid can be difficult. In this case, the large subcapsular component (arrowheads) is compressing the splenic (S) parenchyma, but it is difficult to separate from perisplenic hematoma (arrows). Notice the blood lateral to the liver.

Figure 106-9 Active extravasation of contrast material. There is active extravasation of contrast material from the site of splenic laceration (short arrow). Extravasation of contrast material can be distinguished from the perisplenic hematoma (arrowheads) by its higher density. Notice the extension of the hemoperitoneum to the perihepatic space (long arrow).

Figure 106-10 The sentinel clot sign. Isolated, perisplenic, high-attenuation hematoma (arrow) indicates a high likelihood of splenic injury. The splenic laceration was not apparent.

Figure 106-11 Delayed splenic rupture. Enhanced CT scan of a 17-year-old patient who presented with worsening abdominal and left shoulder pain 1 week after being kicked in the abdomen. A low-attenuation splenic hematoma (H) and associated perisplenic fluid and hemorrhage (arrows) are identified. Splenectomy was required.

dissection of hemorrhage through the splenorenal ligament to the retroperitoneal interfascial planes.⁵⁹

Splenic artery pseudoaneurysm is a rare but life-threatening complication of splenic injury after blunt abdominal trauma. Davis and colleagues⁶⁰ reported well-circumscribed focal contrast blush indicative of pseudoaneurysm formation in the CT of 8% of their adult patients with blunt splenic injury. Pseudoaneurysm may also be diagnosed by ultrasound, but it has lower sensitivity than CT.^{61,62} The current management of post-traumatic splenic artery pseudoaneurysm in adults and children diagnosed by CT or ultrasound is not well established and ranges from conservative treatment to immediate confirmation and embolization by angiography.^{43,60,63-66} A pseudoaneurysm may be distinguished from active extravasation of contrast material by examining the arterial and excretory phases of CT; pseudoaneurysm will become isodense to the adjacent vascular structures on delayed images, whereas active hemorrhage demonstrates no significant change in attenuation. Delayed CT may be obtained with reduced radiation setting without significant degradation of image quality.⁶⁷

Significant intimal injury in the splenic artery may lead to splenic infarction. This unusual finding may be associated with splenic or other adjacent organ injury and may not be associated with significant adjacent hemoperitoneum.⁶⁸

Several case reports have described delayed splenic rupture after initial normal findings on CT scan.^{69,70} It is hypothesized that these uncommon delayed ruptures may result from low-grade venous bleeding that eludes detection by initial clinical examination, imaging, and DPL.⁷¹ This phenomenon should always be remembered by radiologists and trauma physicians, but it should not be viewed as a shortcoming of CT alone. CT scanning has been proved useful in the assessment of patients who present with delayed or remote rupture (Fig. 106-11).⁷⁰ The degree of injury by the Splenic Injury Scale as proposed by the American Association for the Surgery of Trauma (see later for grading of splenic injury) as well as the presence of a pseudoaneurysm must be closely evaluated.⁷⁰ Increase in the size of linear foci on follow-up scans should alert the clinician to the possibility of progression of laceration. A hyperdense focus

within the injured parenchyma after intravenous administration of contrast material may indicate pseudoaneurysm formation. As discussed previously, the role of CT in follow-up of patients with splenic injury who are hemodynamically stable and are without evidence of blood loss has not been clearly established. Many institutions obtain follow-up CT within 48 hours of the initial diagnosis to assess for possible progression of injuries.^{60,71} However, most studies have shown that follow-up CT without a clear clinical indication is not necessary.^{52,54,72,73}

Changes in splenic size on follow-up examinations should be interpreted carefully. Splenic enlargement has been observed in stable patients after blunt trauma, which is believed to represent return to normal size after physiologic contraction. Goodman and Aprahamian⁷⁴ reported an average 25% increase in splenic volume on follow-up CT scans in trauma patients, with more than half of their patients manifesting an average increase in splenic volume of 56%.

CT is equally useful in penetrating injuries, particularly stab wounds. CT can reveal commonly associated chest, diaphragmatic, and intra-abdominal injuries (Fig. 106-12). The use of water-soluble oral and rectal contrast agents facilitates the detection of associated visceral injuries. Munera and coworkers emphasized the role of CT with triple contrast in evaluation of patients with gunshot wound injury who are not immediate exploratory laparotomy candidates.^{75,76} However, this approach is controversial and not universally accepted.^{77,78}

It is important to be aware of interpretive pitfalls in diagnosis of splenic injury by CT. Splenic parenchymal enhancement in normal patients usually appears heterogeneous during the early phase of scanning and should be interpreted with caution in trauma patients (Fig. 106-13). Portal venous phase of enhancement optimizes splenic enhancement for evaluation of traumatic injury. Therefore, start of the scanning approximately 65 seconds after the start of contrast material injection improves hepatic and splenic enhancement. Diminished splenic enhancement relative to liver has been reported in trauma patients without splenic injury, possibly related to adrenergic stimulation and splanchnic vasoconstriction, and should not

necessarily be interpreted as indicative of splenic injury or vascular compromise.⁷⁴

Significant artifact from the patient's arms or overlying support lines may simulate splenic injury or limit its evaluation. Close attention to patient positioning is mandatory, and its importance should be communicated to the trauma team. Respiratory motion artifact mimicking subcapsular hematoma, common with older scanners, is uncommon with the latest multislice scanners. Congenital splenic clefts are common and should not be mistaken for lacerations. Clefts typically are found along the medial surface of the spleen (Fig. 106-14),

Figure 106-12 Penetrating splenic injury. CT scan of a 22-year-old woman who was stabbed in the anterior chest shows a low-attenuation splenic laceration (black arrow) and gas bubbles (curved white arrow) from gastric perforation. The prominent left hepatic lobe (L) is a variant that can abut the lateral margin of the spleen (S).

whereas most lacerations originate from the lateral surface of the spleen.⁷⁹ However, neither of these generalizations is absolute, and at times, clefts may be difficult to distinguish from a laceration.

Surgical and CT Classification of Splenic Injury. Splenic injuries have been anatomically classified by the Organ Injury Scaling Committee of the American Association for the Surgery of Trauma (Table 106-1) to reflect the impact of specific injuries on the patient's therapy and outcome.^{80,81} The Organ Injury Scaling classification is based on the anatomic disruption of the spleen scaled 1 to 5. These represent increasingly complex injuries that affect surgical management.⁸¹ This anatomic system, currently used by most trauma centers, is limited because it does not account for the presence and volume of hemoperitoneum or other organ injuries. Several CT-based grading systems have been created to incorporate this information.^{5,33,82} A splenic injury grading system that takes these findings into consideration has been proposed by Mirvis and colleagues but awaits prospective trial.^{40,43}

Mirvis and colleagues⁴⁰ found that CT is accurate in identifying splenic injury but is not useful in predicting outcomes. CT grading of blunt splenic trauma has been found to be an unreliable predictor of patient outcome by several other investigators also.⁸³⁻⁸⁵ Studies have shown that evidence of active hemorrhage on contrast-enhanced CT and traumatic splenic pseudoaneurysms and arteriovenous malformations indicate higher likelihood of failed conservative treatment.^{55,86,87} Their influence on grading and patient outcome is being studied at several institutions.* Perhaps a common difficulty in such grading is the influence of nonanatomic factors, such as patient age,

*References 37, 43, 56, 60, 65, 66, 86.

Figure 106-13 Heterogeneous enhancement of the spleen. **A.** The spleen appears heterogeneous during the late arterial and early portal venous phases of enhancement. The heterogeneous enhancement mimics intraparenchymal hematomas in this patient with subcapsular hematoma. **B.** Image obtained during the portal venous phase of hepatic enhancement shows the splenic subcapsular hematoma, but the spleen is otherwise unremarkable.

Figure 106-14 Congenital splenic clefts. These commonly observed variants more typically involve the medial aspect of the spleen. When they extend across the spleen, they can be mistaken for splenic laceration or fracture. **A.** A low-attenuation cleft (arrow) is more prominent on the medial aspect of the spleen (S). **B.** A cleft (arrow) traverses the full thickness of the spleen (S).

TABLE 106-1 American Association for the Surgery of Trauma Splenic Injury Scale (1994 Revision)

Grade*	Lesion	Injury Description
I	Hematoma	Subcapsular, nonexpanding, <10% of surface area
	Laceration	Capsular tear, nonbleeding, parenchymal depth <1 cm
II	Hematoma	Subcapsular, nonexpanding, 10%-50% of surface area; intraparenchymal, nonexpanding, <5 cm in diameter
	Laceration	Capsular tear, active bleeding; 1-3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% of surface area or expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal hematoma >5 cm or expanding
	Laceration	Parenchymal depth >3 cm or involving trabecular vessels
IV	Hematoma	Ruptured intraparenchymal hematoma with active bleeding
	Laceration	Laceration involving segmental or hilar vessel producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury that devascularizes spleen

*Advance one grade (up to grade III) for multiple splenic injuries. Modified from Moore EE, Cogbill TH, Malangoni MA, et al: Organ injury scaling. *Surg Clin North Am* 75:293-303, 1995.

overall hemodynamic stability, and preparedness of the trauma center, regardless of the injury grade.* Marmery and associates⁹⁴ incorporated vascular injury and active bleeding in a new grading system for the classification of splenic injury and showed its superiority over the American Association for the Surgery of Trauma system in predicting the need for angiography and embolization or splenic surgery in patients sustaining blunt splenic injury. Further prospective studies are required to validate these results.

Ultrasound

Ultrasound is the primary imaging modality of trauma patients in many centers outside the United States. Its use in the United

States has also increased significantly during the past two decades, with 79% of level I trauma centers currently performing focused assessment with sonography for trauma (FAST).⁹⁵⁻⁹⁷ FAST has two significant advantages over CT: it can be performed at the bedside with hand-held devices and uses no ionizing radiation.⁹⁸ The primary goal of FAST is detection of free intraperitoneal fluid. This is based on the assumption that significant intra-abdominal injury is unlikely without the presence of free intraperitoneal fluid. Its reported sensitivity for detection of free intraperitoneal fluid ranges between 42% and 98%.^{10,97,99-101} Several studies have shown significant false-negative and false-positive rates in both adult and pediatric patients, casting doubt on the utility of FAST.^{8,9,102-104} Investigators have shown decreased sensitivity of FAST when patients are stable.^{26,99,105,106} This may be related to operator dependence of ultrasound as well as lack of free intraperitoneal free fluid with less severe injuries. In addition, ultrasound has limited sensitivity for detection of retroperitoneal injuries.^{103,107-109} Furthermore, patient obesity, subcutaneous emphysema, and limited acoustic window as well as isoechoic clot can limit its sensitivity.¹¹⁰

The detection of intraparenchymal and subcapsular lesions depends on the sonographic appearance of hemorrhage, which in turn is dependent on the age of the blood and frequency of the interrogating transducer. In the acute setting, lacerations and hematomas appear echogenic because of the presence of clotted blood. Both fresh and chronic hemorrhage can appear hypoechoic (Fig. 106-15).^{111,112} Because the liver is usually less echogenic than the spleen, the left hepatic lobe that extends to the left upper quadrant of the abdomen and indents the spleen may simulate a subcapsular hematoma of the spleen sonographically (Fig. 106-16). Scanning should also include a general survey to detect hemoperitoneum within the abdomen. The detection of blood surrounding the gastrosplenic ligament, the “left butterfly” sign, has been reported to indicate hemorrhage within the lesser sac and should direct the sonographer to the possibility of splenic, gastric, or pancreatic injury.¹¹¹ Color Doppler study may help in detection of intrasplenic pseudoaneurysm.⁶¹ Contrast-enhanced sonography for the evaluation of splenic trauma has been reported to be more sensitive than a baseline sonogram, but its wide acceptance awaits larger trials.^{62,113-116}

The relatively lower accuracy of ultrasound compared with CT and DPL for detection of intra-abdominal injury suggests that this modality has a complementary rather than a

*References 6, 40, 43, 57, 63, 72, 80, 88-93.

Figure 106-15 Ultrasound diagnosis of splenic injury. Correlative ultrasound scan of a 19-year-old with known splenic laceration, splenic cleft, and perisplenic fluid to diagnose splenic injury. **A.** An oblique coronal image obtained intercostally demonstrates hypoechoic perisplenic fluid (F) adjacent to the spleen (S). **B.** A companion oblique image illustrates the perisplenic fluid (F) and the known splenic cleft (arrow). The patient's CT-diagnosed splenic laceration was not observed sonographically.

Figure 106-16 Splenic vein thrombosis. The patient has extensive splenic and hepatic lacerations and splenic vein thrombosis (arrow).

competing role with CT and DPL.^{96,117-120} All patients with normal findings at the initial FAST should be observed for several hours to avoid missing of significant injuries. In addition, serial ultrasound or CT examinations should be obtained in those with suspected significant injuries.^{110,121,122} A principal role of ultrasound today is in the postoperative patient and for long-term follow-up of patients treated conservatively. Sequential sonograms can be used to document resolution of splenic parenchymal abnormalities and to monitor the volume of hemoperitoneum.

Other Techniques

The technetium Tc 99m sulfur colloid scan has been shown to be a sensitive albeit somewhat nonspecific test in splenic trauma.¹²³ Scintigraphy, however, no longer has a role in assessment of blunt abdominal trauma. Likewise, angiography is no longer appropriate as a screening modality but has been shown

to be effective in identifying specific sites of injury determined by CT and provides access for therapeutic embolization of splenic bleeders.¹²⁴

Plain film findings in traumatized patients are usually non-specific. Abnormal findings suggesting splenic trauma include posterior left rib or upper lumbar transverse process fractures, medial displacement of gastric air bubble, elevation of the left hemidiaphragm, and signs of hemoperitoneum. However, lack of abnormal findings on chest or abdominal films does not obviate the need for further diagnostic evaluation.

COMPLICATIONS OF SPLENIC INJURY

Complications of splenic injury depend on the mechanism of injury and the choice of therapy. In patients treated conservatively or with spleen-preserving surgery, the principal concern is rebleeding. Other sequelae include spontaneous splenic vein thrombosis, splenic abscess formation, pancreatitis, and intra-abdominal or thoracic splenosis.¹²⁵⁻¹²⁷ When splenectomy is required, typical postoperative complications include left lower lobe atelectasis, pneumonia, and pleural effusions. Subphrenic abscess, disseminated intravascular coagulopathy, and pancreatic injury are less commonly observed complications.¹²⁸

The major concern in the postsplenectomy patient is the loss of splenic immune functions and the risk of overwhelming postsplenectomy sepsis.^{129,130} The incidence of overwhelming postsplenectomy sepsis after trauma varies from 0.28% to 1%, and mortality is reported to be as high as 50% to 80%.^{131,132} The syndrome of overwhelming postsplenectomy sepsis is characterized by the systemic symptoms of nausea, vomiting, and malaise that rapidly progress to coma, hypotension, and death within hours of the onset of symptoms. There is usually a sub-clinical focus of infection by encapsulated organisms, such as *Streptococcus*, *Haemophilus*, or *Neisseria*. In addition, postoperative infectious complications are much more frequent in splenectomized patients. The risk of septicemia in asplenic has been estimated to be 140 times greater than in the general population. Patients undergoing splenectomy have longer hospital stays than those conservatively managed.^{31,129,132}

TREATMENT AND OUTCOME

Recognition of the importance of preserving splenic function has led to a dramatic shift in surgical opinion and practice. Nonoperative management of splenic injury in pediatric patients is the norm and is successful in more than 90% of appropriately selected patients.^{133,134} Although the nonoperative approach to pediatric splenic injury is well established, application of this practice to adult trauma patients is still evolving but gaining wider acceptance.^{81,135-138} Although age older than 55 years has been considered a criterion for operative management, Barone and coworkers¹³⁹ and Myers and colleagues⁹² reported a failure rate of 6% and 17% for nonoperative management of patients older than 55 years, respectively. Grade of splenic injury rather than age was reported to play an important role in outcome by Nix and coworkers.⁶ Success rates in adults have ranged from 27% to 90%.^{137,138} Major criticisms directed toward nonoperative management include failure to detect associated injuries, such as bowel perforation or diaphragmatic disruption, and an increase in transfusion requirements. Some authors have suggested that the risk-benefit ratio for nonoperative management is exceeded by transfusion risks posed by administration of more than 2 units of blood or presence of a significant amount of hemoperitoneum on CT.^{140,141} Patients should meet strict criteria for consideration of nonoperative treatment: low-grade and isolated splenic injury, hemodynamic stability, and mental alertness.¹⁴² In this regard, CT evaluation may be useful in selecting patients who are inappropriate for nonoperative treatment and would benefit from early spleen-preserving surgery. Most patients (up to 85%) are now managed nonoperatively as some of the previous expert consensus contraindications mentioned earlier (e.g., advanced age, fear of missing a hollow viscus injury, >2 units of packed red blood cell transfusion) are no longer completely valid.^{143,144}

Splenic artery embolization has been shown to improve outcome of nonoperative management.^{60,64,143,145-149} Haan and associates¹⁵⁰ reported a splenic salvage rate of 87% by embolization. In their series, more than 80% of splenic injury grades 4 and 5 were successfully managed nonoperatively. Patients older than 55 years had outcome similar to that of the younger patients. Complications were seen in 16 of 140 patients, with bleeding and abscess representing the most frequent complications. A more recent study has shown similar outcome for main artery coil embolization versus selective or combined embolization techniques.¹⁵¹ Higher splenic injury score, lower blood pressure, lower pH, and increased number of packed red blood cell transfusions are factors that favor an operation over embolization.¹⁵² However, successful transcatheter arterial embolization for splenic injury has been reported in hemodynamically unstable patients.¹⁵³ CT after embolization is indicated if there is abdominal pain, hypotension, or signs of infection. Gelfoam used in embolization may appear as gas within the infarcted area.¹⁵⁴

An important alternative to nonoperative management is the splenic salvage procedure, in which either a simple splenorrhaphy or more complex segmental resection with repair is performed.³³ These procedures have led to success rates of more than 95%.¹⁴⁰

Splenic Surgery

After splenectomy for traumatic lesions is excluded, most splenectomies are performed for control or evaluation of

hematologic or neoplastic disease. Regardless of the reason for splenectomy, the principal surgical consideration is adequate mobilization of the spleen. Because of the intimate association of the stomach and colon with the spleen, inadvertent injuries can occur intraoperatively, with postoperative abscess being the primary complication. Similarly, the pancreatic tail is usually found to extend into the splenic hilum and can be injured during splenectomy. The significant incidence of postoperative complications, including pancreatitis, pancreatic fistula, and pseudocyst, has led to considerable debate among surgeons as to whether the splenectomy bed should be routinely drained. Laparoscopic splenectomy, now practiced in many centers, has a lower morbidity and hospital stay compared with open splenectomy.¹⁵⁵⁻¹⁵⁷ However, it poses certain technical challenges, such as management of the massive spleen, specimen extraction, and identification of remotely located accessory spleens.^{158,159} Portal or splenic venous thrombosis is a more frequent complication of laparoscopic splenectomy and can be treated safely.¹⁶⁰ In one study, the incidence of portal or splenic venous thrombosis was shown to be around 20% at 1 week on Doppler ultrasound evaluation. The authors recommended ultrasonographic screening for portal or splenic venous thrombosis at postoperative day 7.¹⁶¹ Multidetector CT angiography with volumetric and anatomic evaluation provides accurate and reproducible information for planning of laparoscopic splenectomy.¹⁶²

The radiologic evaluation of the postsplenectomy patient is performed for evaluation of infection, hemorrhage, or pancreatic injury. Because of these indications and the usual limitations of ultrasound in the left upper quadrant, CT is the preferred modality. Adequate oral or rectal contrast material is important for evaluation of the splenectomy bed. The ability of CT to distinguish sterile postoperative collections from abscess is limited, and percutaneous aspiration is important. Subphrenic abscess (Fig. 106-17) can be difficult at times to distinguish from pleural fluid collections. Percutaneous management of subphrenic abscess by CT guidance can be performed.

Figure 106-17 Subphrenic abscess after splenectomy. A large, left, upper quadrant air-fluid collection (A) compresses the stomach in a patient after splenectomy for trauma. A large subphrenic abscess was drained at reoperation.

Pelvic Peritoneal Spaces

The peritoneum, subperitoneal space, and retroperitoneum are anatomic compartments frequently involved in pathologic processes that originate in the gastrointestinal tract. Because they represent the result of complex embryologic processes of organogenesis, rotation, folding, and fusion, the distribution of fluid collections resulting from such processes is often confusing. A working knowledge of the anatomic compartmentalization of disease spread in the abdomen is essential to the understanding of imaging findings in a variety of pathologic conditions.

This chapter focuses on the anatomy of the peritoneum, retroperitoneum, and subperitoneum as depicted by cross-sectional imaging methods. In normal individuals, the boundaries of these anatomic regions are defined poorly or not at all. When pathologic processes produce intra-abdominal fluid collections, the patterns of fluid distribution are directly determined by their relationships. The patterns of disease spread within the abdomen can be logically predicted from an understanding of the folds of mesenchymal tissue that envelop the

gut and the gut-derived solid viscera: the mesenteries. Most illustrations in this chapter feature the axial sections familiar to all practitioners of computed tomography (CT) and magnetic resonance imaging (MRI). In selected examples, however, the anatomic relationships are better displayed by coronal, sagittal, or volume rendered images.

Embryology

Embryology is the key to understanding all of the concepts presented in this chapter. This section provides an overview of the embryogenesis of the retroperitoneum and the mesenteries that form ligamentous attachments in the adult.¹ Some details are addressed in the sections on retroperitoneum and subperitoneum that follow.

UPPER ABDOMINAL EMBRYOGENESIS

The Gut and Its Derivatives

At about 3 weeks of fetal life, the lateral body plates (the mesodermal tissue forming the external fetal surface) of the fetus curl up to enclose a small portion of the celomic cavity to form an intraembryonic celomic cavity (Fig. 108-1A). Near the umbilicus, a portion of the yolk sac, which gives rise to the endodermal structures (the gut and all gut-derived solid organs), is enclosed and lined on all sides by fetal mesoderm. At this stage, there are well-demarcated right and left peritoneal spaces, divided by the mesenchyme suspending the gut from the ventral body wall (i.e., ventral mesentery), the gut and its surrounding mesenchyme, and the mesenchyme suspending the gut from the dorsal body wall (i.e., dorsal mesentery). Maternal blood from the umbilical vein courses through the ventral mesentery to supply the fetus, and blood from the now paired dorsal aortae establish vascular channels to the gut and developing viscera through the dorsal mesentery.

At about 4 weeks of fetal development, this symmetric arrangement is distorted. The liver begins to develop in the middle of the ventral mesentery, and it grows rapidly in all directions, bulging the contour of the right and left ventral peritoneal space and extending superiorly inside the ventral mesentery until it encounters the septum transversum (i.e., fetal diaphragm), which is growing from the ventral to the dorsal wall of the fetus to separate the thoracic from the abdominal cavity. The broad, roughly oval line of contact between the ventral mesentery and the septum transversum is not lined by mesothelium, and it becomes the bare area of the liver in the adult (Fig. 108-1B, C).

At the same time, the spleen and pancreas are beginning to grow within the leaves of the dorsal mesogastrium (Fig. 108-1D). The spleen generates just dorsal to the stomach, whereas

Figure 108-1 Embryogenesis of peritoneal spaces and ligaments. **A.** By the end of the third week of fetal development, the ventral body wall has fused, forming an enclosed abdominal cavity with the pinched-off primitive gut (G) in the center. The primitive gut is suspended within the abdomen by the dorsal (arrow) and ventral (arrowhead) mesenteries, which divide the cavity into symmetric right and left halves. **B.** Formation of the bare area of the liver. The line drawing of a sagittal view of an embryo from the left side shows the liver (L) within the ventral mesentery that is growing cephalad to encounter the mesoderm within the septum transversum (st). The surface of the liver in contact with the septum transversum (arrows) is not peritonealized and is known as the bare area. **C.** The line drawing depicts the rotation of the bare area into its adult position. As the septum transversum grows dorsally to separate the thorax from the abdomen, the bare area (arrows) shifts to a posterior position within the abdominal cavity. **D.** During the fourth week of fetal life, cords of tissue from the dorsal and ventral mesenteries grow rapidly, forming the liver, the spleen, and the tail off the pancreas. The liver (arrowhead) arises within the ventral mesentery. The spleen and the body and tail of the pancreas (arrow) grow from the dorsal mesentery. **E.** During the fifth week, the liver begins to grow rapidly and begins to occupy a large portion of the peritoneal space. Concurrently, the right peritoneal space expands toward the left, extending posterior to the stomach. **F.** The leftward expansion of the right peritoneal space causes the gastrosplenic ligament to billow laterally (arrowheads). The tail of the pancreas (P) fuses with the dorsal mesenchymal tissue. A, Aorta; FL, falciform ligament; GHL, gastrohepatic ligament; GSL, gastrosplenic ligament; K, kidney; L, liver; S, spleen; SRL, splenorenal ligament; ST, stomach.

the dorsal pancreas arises behind the duodenum. Part of the pancreas (i.e., the head and uncinate process in the adult) arises from a nest of cells within the ventral mesentery that ultimately rotates to join the dorsal pancreas later in fetal life. The all-enveloping mesenchyme continues to connect all of these developing organs with the body wall and the gut, and it persists into adult life as the abdominal ligaments (Fig. 108-1E). The ventral part of the ventral mesentery, connecting the liver to the anterior body wall, becomes the falciform ligament, through which courses the umbilical vein (and its fibrous remnant, the ligamentum teres, in the adult). The dorsal part of the ventral mesentery becomes the gastrohepatic and hepatoduodenal ligaments, which together compose the lesser omentum. The gastrohepatic ligament stretches between the lesser curvature of the stomach and the fissure for the ligamentum venosum. It contains the left gastric artery and vein and the lymph node group that drains the lesser curvature. The hepatoduodenal ligament, the caudal extension of the lesser omentum, contains

the portal vein, hepatic artery, common bile duct, and hepatic lymph node chain. The most inferior edge of the lesser omentum forms the roof of the foramen of Winslow.

The ventral part of the dorsal mesentery, connecting the stomach to the spleen, becomes the gastrosplenic ligament, identified by the short gastric arteries and veins that course within it (Fig. 108-1F). In the adult, the gastrosplenic ligament also forms the entirety of the greater omentum (i.e., gastrocolic ligament) and the cephalad portion of the transverse mesocolon (discussed later). These fat-filled structures are readily identified by their contained vessels, the gastroepiploic in the greater omentum and the middle colic in the transverse mesocolon. The dorsal part of the dorsal mesentery becomes the splenorenal (lienorenal) ligament, which contains the splenic vessels and connects the spleen with the tail of the pancreas. This latter mesenchyme fuses almost completely with the anterior renal fascia to become part of the retroperitoneum.

Figure 108-2 Formation of the gastrocolic ligament and transverse mesocolon. **A.** The leftward expansion of the right peritoneal cavity has elongated the gastrosplenic ligament caudally, forming an inferior recess of the developing lesser sac (arrowheads). Long arrow, small bowel mesentery; short arrow, transverse mesocolon. **B.** The posterior layer of the gastrosplenic ligament eventually fuses with the colonic mesentery to form the transverse mesocolon (arrow). The anterior and posterior layers of the gastrosplenic ligament also fuse to obliterate a portion of the right peritoneal space and in so doing form the gastrocolic ligament (arrowhead). What remains of the expanded retrogastric portion of the right peritoneal space eventually becomes the lesser sac (LS). C, transverse colon; D, duodenum; I, small intestine; P, pancreas; ST, stomach; arrows, mesenteries of the colon and small intestine.

During the fifth and sixth weeks of fetal life, the liver continues to grow rapidly and rotates into the right peritoneal space. Concurrently, the stomach undergoes a 90-degree clockwise rotation, such that its left side becomes ventral and its right side dorsal. This rotation pulls the dorsal mesogastrium to the left, allowing room for the right peritoneal space to expand behind the stomach and in front of the pancreas.

This part of the right peritoneal space becomes the lesser sac (i.e., omental bursa). The inferior margin of the gastrosplenic ligament elongates in a caudal direction to form a long inferior sinus. Later in fetal life, the redundant apposed layers of this part of the gastrosplenic ligament fuse to form the greater omentum (Fig. 108-2). During this period (roughly week 6 of fetal development), the midgut has lengthened to the extent that its midportion projects into the umbilical cord (i.e., physiologic herniation). During the 10th week, it returns to the abdomen. The cecum ultimately undergoes a 180-degree rotation (as viewed from above) to arrive at its normal location in the right lower quadrant. The ascending and descending colonic segments undergo further rotation such that their mesenteries fuse to the anterior renal fascia on each side (Fig. 108-3). On the right, the ascending colon rotates 90 degrees counterclockwise (as viewed from below) and normally becomes a fixed part of the retroperitoneum. On the left, the descending colon rotates 90 degrees clockwise (as viewed from below) to become a portion of the retroperitoneum. The transverse colon and its mesentery span the fetus from right to left, with a mesenteric surface facing ventrally. The posterior part of the gastrosplenic ligament then fuses with this surface to form the adult transverse mesocolon.

Figure 108-3 Rotation and fusion of colon mesentery. **A.** The line drawing of an embryo early in fetal development shows the distal midgut and hindgut segments that become the adult colon. The most caudal portion, the rectum (R), retains its position in the pelvis. The descending colon (DC) and its attached dorsal mesentery rotate (curved arrow) to cover the surface of the left kidney (LK). The more proximal portions, including the cecum (C) and ascending colon (AC), elongate and join the remainder of the midgut within the physiologic herniation through the umbilicus that occurs in about the sixth fetal week. When these segments return to the abdomen, they undergo a hairpin turn (arrow) so that the cecum is positioned in the right lower quadrant. **B.** After its relocation, the right colon and its attached mesentery rotate to cover the anterior surface of the right kidney (RK). The transverse colon (TC) and its mesentery (MES) face anteriorly at roughly the same level as the pancreas (P).

LOWER ABDOMINAL AND PELVIC EMBRYOGENESIS

Rectum, Urogenital Sinus, and Kidneys

The rectum and urogenital sinus initially develop as part of one structure, the cloaca, the distal part of the hindgut.² As the fetus develops, the urorectal fold, a peritoneal sinus, divides the anterior urinary system from the posterior gut (Fig. 108-4A). In the adult, the caudal part of the urorectal fold fuses to become Denonvilliers' fascia, but a sulcus of peritoneum persists in males and females, becoming the rectovesical pouch (i.e., pouch of Douglas). The rectum and perirectal fat are enveloped by an important fascial plane, the mesorectal fascia.

The anterior (urinary tract) system has several connections that determine adult anatomic landmarks. Superiorly, the urogenital sinus is connected to the umbilical stalk through the allantois, which undergoes fibrous degeneration to become the urachus in both sexes. Posteriorly, the midportion of the urogenital sinus (which becomes the urinary bladder) receives the metanephric duct, or ureter. The inferior part of the urogenital sinus receives the paramesonephric duct and the mesonephric duct; further development of the sinus and the two ducts it receives depends on gender differentiation. In the female embryo, the inferior parts of the paramesonephric ducts fuse to become the uterus and upper vagina, and the part closest to the gonad becomes the fallopian tube. The mesonephric duct almost completely degenerates. The inferior aspect of the urogenital sinus becomes the urethra, lower vagina, and vestibule, with associated Bartholin's glands (Fig. 108-4B).

In the male embryo, the paramesonephric ducts degenerate. The portion of the mesonephric duct closest to the gonads becomes the ductus deferens, and the part closest to the

Figure 108-4 Embryology of the pelvis. **A.** Sagittally oriented line drawing of the pelvis in a developing fetus before gender differentiation shows the urorectal sinus (urs), a fold of peritoneum that divides the cloaca into a posterior alimentary tract component, including the rectum (R), and an anterior urogenital component (ugs). The central portion of the urinary component is the bladder (B), which drains superiorly into the allantoic stalk, which becomes the urachus (ura). Inferiorly, the bladder is attached to the urogenital sinus (urs), which differentiates further according to gender. The bladder receives the ureter (ur), and the urogenital sinus receives the paramesonephric duct (pmd) and the mesonephric duct (md), both of which contribute to genital formation. **B.** In the female, the mesonephric duct is almost completely resorbed; its superior portion becomes the ligamentum teres (lt). The central fused portion of the paramesonephric ducts becomes the uterus (ut), and the more superior paired portions close to the ovaries (ov) become the fallopian tubes (ft). The inferior paramesonephric duct becomes the superior vagina (svag). The urogenital sinus in females differentiates into the inferior portion of the vagina (ivag) and urethra (ure). **C.** In males, the paramesonephric duct (pmd) is resorbed. The portion closest to the testis (tes) becomes the vas deferens, and the part near the urogenital sinus differentiates into the seminal vesicles (sv). The urogenital sinus becomes the prostate (pr) and penile urethra (ure). k, Kidney; vd, vas deferens.

urogenital sinus develops into the seminal vesicles and ejaculatory duct. Meanwhile, the urogenital sinus becomes the prostate, urethra, and associated glands (Fig. 108-4C). The remnant of this embryologic derivation is a fascial plane (i.e., umbilicovesical fascia) that envelops the extraperitoneal portion of the bladder and is continuous with the structures that were embryologically in communication with the bladder surface. These structures include the urachus (i.e., median umbilical ligament), the obliterated umbilical arteries (i.e., medial umbilical ligaments), and, in males, the ductus deferens, seminal vesicles, and prostate. This fascia also covers the medial aspect of the ureters as they insert into the bladder base (see Fig. 108-15).

Retroperitoneal Anatomy: Spaces

The embryology previously discussed provides a rationale for the laminar nature of the retroperitoneum (Fig. 108-5). We consider four layers, proceeding from the outermost portion of the extraperitoneum (i.e., body wall and great vessels) to the innermost (i.e., anterior pararenal space). The basic concept to be stressed is that pathologic fluid collections rapidly fill their space of origin and then extend into some nearby expandable plane. If the origin of the fluid collection is within what was embryologically a mesentery (e.g., pancreatitis within the dorsal mesentery), a common mode of extension is within the ligament to which it is attached (e.g., the gastrosplenic ligament). This method of extension is known as subperitoneal spread, as shown in Figure 108-5A. Alternatively, fluid collections may progress between the layers that make up the retroperitoneal lamina (e.g., between the anterior pararenal space and the perirenal space). This is known as interfascial spread,³⁻⁹ and it provides potential communication between the upper abdomen and the pelvis (Fig. 108-5B, C). The remainder of this section provides clinical images of each form of spread, including examples of fluid and aggressive cellular collections.

GREAT VESSELS

The aorta and inferior vena cava course through an incompletely margined space in front of the vertebrae and anterior psoas fascia and posterior to the root of the small intestinal mesentery. An incomplete lateral boundary is formed by the medial aspect of the anterior and posterior renal fasciae, but this is pierced by the renal artery and vein. Superiorly, the great vessel space is continuous with the middle mediastinum; inferiorly, it extends between the abdominal portions of the ureters. Processes that begin in this space can extend easily into the perirenal fat or into the planes anterior and posterior to the perirenal space (Fig. 108-6).¹⁰⁻¹³ Hemorrhage from ruptured aortic aneurysms is particularly likely to enter the posterior interfascial plane. Other processes, such as retroperitoneal fibrosis, tend to be restricted to the great vessel space, encompassing the aorta and inferior vena cava and extending to involve both ureters in their abdominal course.

TRANSVERSALIS FASCIA

The transversalis fascia is the expandable plane that lines the inner surface of the entire abdominal wall. It forms the outermost layer of the retroperitoneum. It is continuous with the diaphragmatic fascia superiorly and with the deep pelvic fascia inferiorly, so that it provides a natural pathway for fluid collections to spread throughout the abdominal cavity.

POSTERIOR FAT PADS

There are two fat pads that provide a cushion for the kidneys; they are positioned in the posterolateral portion of the abdomen and extend into the upper portion of the pelvis. The larger of the two is a crescentic fat collection, the anterior part of which lies lateral to the ascending and descending colon; the posterior part lies on the posterior surface of the perirenal

Figure 108-5 The layers of the retroperitoneum and concepts of fluid distribution. **A.** The line drawing depicts the four major retroperitoneal layers. The outermost is the transversalis fascia (tf), which extends from the inferior diaphragmatic fascia to the deep pelvic fascia and surrounds all abdominal organs. Just deep to the transversalis fascia, there are two organless fat pads. The posterior fat pad (pfp) is located just anterior to the quadratus lumborum muscle (qlm). The larger posterolateral fat pad (plfp) cushions the kidney (K) and perirenal fat and the mesentery surrounding the descending colon (DC). Between the two is a cleft, which is a part of the inferior lumbar triangle; the cleft is an important passageway between the deep retroperitoneum and the transversalis fascia. Just internal to the fat pads are the perirenal spaces (prs), which contain the kidneys, adrenal glands, and abundant fat. They are bounded by expandable fascial planes anteriorly (arf) and posteriorly (prf). They are loosely attached medially to the great vessel space around the inferior vena cava (IVC) and aorta (A). In adults, the two perirenal spaces do not communicate directly. The innermost space, which is the anterior pararenal space (aps), is composed of the dorsal mesenteries that contain the ascending (AC) and descending colon (DC) laterally and the duodenum (D) and pancreas (P) medially. **B.** The concept of subperitoneal disease spread is delineated. The line drawing of an early embryo emphasizes that the mesenteries surround every structure in the abdomen, providing a potential means of communication by way of the abdominal ligaments (derivatives of the mesenteries); the falciform ligament (fl) connects the liver (L) with the anterior abdominal wall. The stomach (ST) and duodenum are connected to the liver by the gastrohepatic ligament (ghl) or lesser omentum. The dorsal mesentery, containing the spleen (SP) and pancreas, communicates ventrally through the gastrosplenic ligament (gsl) and dorsally by way of the splenorenal ligament (srl). **C.** The diagram shows the retroperitoneal compartments and interfascial planes and spaces. The anterior pararenal space (APS) contains the duodenum (not shown), the ascending and descending colon, and the pancreas. The perirenal space contains the adrenal glands (not shown) and the kidneys. The perirenal spaces are closed medially. The posterior pararenal space (PPS) contains fat and lymph nodes. The renal fascia and lateroconal fascia are laminated planes composed of apposed layers of embryonic mesentery. By dissection of these layers, rapidly accumulating fluid collections or infiltrating disease may spread within retroperitoneal fascial planes. The thickness of the interfascial planes is exaggerated to illustrate their potentially expansile nature; all three interfascial planes are potential spaces. The retromesenteric plane (RMP) is continuous across the midline (bidirectional arrows). The retromesenteric plane, retrorenal plane (RRS), and lateroconal plane (LCF) communicate at the fascial trifurcation (arrow). The dorsal pleural sinus (DPS) may extend inferiorly to lie posterolateral to the PPS and the transversalis fascia (TF). ARF, Anterior renal fascia; PP, parietal peritoneum; PRF, posterior renal fascia. (C from Aizenstein RI, Wilbur AC, O'Neil HK: Interfascial and perinephric pathways in the spread of retroperitoneal disease: Refined concepts based on CT observations. *AJR Am J Roentgenol* 168:639-643, 1997.)

fat. This fat has been called the posterior pararenal space. Cutaneous nerves pass through this fat, but it contains no organs and is rarely the primary site of pathologic processes. The smaller fat pad lies just anterior to the transversalis fascia near the quadratus lumborum muscle. Between the two fat pads is a cleft, through which fluid may pass from the deep retroperitoneum outward to the transversalis fascia. Hernias containing fat or bowel can pass through this same cleft, which is a part of the inferior lumbar triangle (i.e., Petit's triangle). It is common for severe pancreatitis to spread by this route, producing inflammation or hemorrhage, or both, in the ipsilateral

flank; this is the rationale for the Grey Turner sign of hemorrhagic pancreatitis (Fig. 108-7).¹⁴

PERIRENAL SPACE

There has been considerable interest in delineating the precise anatomy of the perirenal space and its enveloping fascia,¹⁵⁻²⁰ and there is no universal agreement about its exact boundaries—whether its inferior part is open or closed to the pelvis²¹⁻²⁸ and whether the spaces communicate across the midline.²⁹ In our view, rapidly expanding retroperitoneal fluid collections extend

Figure 108-6 Ruptured abdominal aortic aneurysm. Scans obtained at two different levels (**A** and **B**) show hemorrhage in the retromesenteric plane (RMP) and the retrorenal plane (arrow). A, aortic aneurysm.

Figure 108-7 Inferior lumbar triangle pathway. **A.** Section from a cadaver shows the posterior fat pad (pfp) just lateral to the psoas muscle (PM) and anterior to the quadratus lumborum muscle (qlm). The posterolateral fat pad (plfp), also called the posterior pararenal space, has been displaced in this subject by a hernia (curved arrow) containing fat adjacent to the descending colon (DC). This inferior lumbar hernia occurs through the cleft between the two fat pads. **B.** Coronal CT section in a patient with severe pancreatitis shows pancreatic effusion from the deep retroperitoneal planes extending (curved arrow) through the inferior lumbar triangle pathway between the posterior fat pad (PFP) and the posterolateral fat pad (PLFP) to reach the transversalis fascia (TF). On the axial image (**C**), notice the preserved fat in the perirenal space (PRS), which divides the anterolateral retromesenteric plane (RMP) from the posterolateral retrorenal plane (RRP).

into the interfascial planes, where they can freely spread into the pelvic extraperitoneum and across the midline (examples are discussed later).

The embryology of the kidneys provides the explanation for the unusual appearance of the perirenal space. As the kidneys ascend from their pelvic origins, they are sheathed by a long, tapered cone of fat within the anterior and posterior renal fascia.³⁰ This space is thin at the diaphragm, typically most voluminous posterior to the lower renal pole, and thin again as

it extends inferiorly toward the pelvis. Fluid collections, such as urinomas or localized hematomas,³¹⁻³⁶ often gravitate toward the posteroinferior portion of the perirenal fat, which typically has the greatest volume. The lateral boundary of the perirenal space abuts the posterolateral fat pad, and its fusion with that space creates an expandable plane that extends behind and lateral to the kidney, the retrorenal plane. The laminar nature of this fusion plane was described by Raptopoulos and colleagues³⁷ and conforms to clinical observations. The anterior

Figure 108-8 Retromesenteric and retrorenal escape planes. **A.** Photograph of a cadaver dissection prepared by injection of blue latex into the pancreatic parenchyma to simulate pancreatitis. The dissector retracts the descending colon (DC) and its mesentery (DCM) to expose the latex in the retromesenteric plane (RMP). This plane lies anterior to the left renal fascia (LRF) and just posterior to the pancreatic (P) tail. **B.** Cross section of a cadaver prepared as in **A** shows yellow latex filling the retromesenteric plane (rmp) anterior to the perirenal space (PRS), which contains the left kidney (LK) and adrenal (ad). Anterior to the latex collection lie the pancreas (P) and descending colon (DC) within the anterior pararenal space (APS), located above the spleen (SP). **C.** CT demonstrates retroperitoneal anatomy in a patient with pancreatitis. The effusion lies in the retromesenteric plane (RMP) anterior to the perirenal space (PRS) around the left kidney (LK). Anterior to the effusion is the anterior pararenal space (aps, identified by its contents), the descending colon (DC), and its mesentery, which is marked by the inferior mesenteric vein (IMV) that is near the pancreas (P). The small intestinal mesentery (SMBM) lies anterior to the anterior pararenal space. **D.** The CT section shows the symmetric arrangement of the intrafascial planes on the right in a patient with inflammation of the duodenum (D). The retromesenteric plane (RMP) lies anterior to the right kidney (RK) and surrounding fat in the perirenal space (PRS) and lies posterior to the ascending colon (AC) and its fat-filled mesentery in the anterior pararenal space (APS). In this example, fluid extends posteriorly between the posterolateral fat pad (PLFP) and the anterior pararenal space within the lateroconal plane (LCP) as well as posteriorly between the perirenal fat and the posterolateral fat pad in the retrorenal plane (RRP). The pancreas (P) and small intestinal mesentery (SMBM) are identified. **E.** Sagittal reformatted CT image of the fascial planes in a patient with severe necrotizing pancreatitis shows fluid expanding the retromesenteric plane (RMP). The plane lies anterior to the right kidney (RK) within the perirenal space (PRS). There is a smaller amount of fluid in the retrorenal plane (RRP) lying posterior to the perirenal space and anterior to the posterolateral fat pad (PLFP). Notice the long inferior continuation of perirenal fat and the transverse colon (TC). **F.** Sagittal reformatted CT image shows the retrorenal plane (RRP) lying behind the perirenal space (PRS) in another patient with pancreatitis. In this case, the fluid extends from the inferior diaphragmatic fascia beyond the level of the lower pole of the left kidney (LK).

boundary of the perirenal space abuts the anterior pararenal space and produces a similar laminar plane (i.e., retromesenteric plane) that also collects and distributes retroperitoneal effusions (Fig. 108-8).

Each perirenal space contains the kidney, adrenal gland, proximal ureter, renal artery, and renal vein. The fascial lining of the perirenal space is incomplete where the renal vessels pass through it, and the entire medial boundary of the space is poorly defined.³⁸ The study by Kunin³⁹ established that there

are well-structured pores within the perirenal fat, some of which course between one surface of the kidney and another (i.e., renorenal septa) and some of which communicate between the renal surface and the perirenal fascia (i.e., renofascial septa). The latter are responsible for the rapid egress of effusions (often urinomas⁴⁰) in the perirenal space into the retromesenteric or retrorenal plane (Fig. 108-9) and for involvement of the renal surface with effusions of extrarenal origin, such as pancreatitis.⁴¹⁻⁴³

Figure 108-9 Perinephric space. **A.** Diagram depicting the perinephric space at the level of the midpole of the right kidney shows a rich network of bridging septa (arrows), arteries, veins, and lymphatics. The perirenal lymphatics communicate with the lymph nodes of the renal hilum, and these connect with the periaortic and pericaval lymph nodes. **B.** Renal pericapsular hematoma can spread along the perinephric bridging septa (arrows) toward the interfascial planes. Tense fluid collections, such as large urinomas and hematomas, that would otherwise be constricted by an intact renal capsule or by perinephric septa may decompress along perinephric channels and retroperitoneal interfascial planes. **C.** Fat-suppressed magnetic resonance image demonstrates bridging septa of Kunin (arrows) in a patient with recent forniceal rupture. **D.** Subcapsular hematoma of the right kidney is decompressing through the bridging septa (white arrows) into the posterior retrorenal plane (red arrow). (**A** and **B** from Aizenstein RI, Wilbur AC, O'Neil HK: *Interfascial and perinephric pathways in the spread of retroperitoneal disease: Refined concepts based on CT observations.* *AJR Am J Roentgenol* 168:639-643, 1997.)

ANTERIOR PARARENAL SPACE

The anterior pararenal space is entirely composed of visceral structures and their mesenteries of origin. Medially, the components consist of the pancreas (with remnants of the ventral mesentery surrounding the head and uncinate process and the dorsal mesentery supporting the neck, body, and tail) and the duodenum. These structures fuse posteriorly with the perirenal space, typically at the level of the renal hila. In the midline, the fusion plane passes between the great vessel space and the root of the intestinal mesentery. This part of the retromesenteric plane provides communication between the left and right retroperitoneum, and it is the only anatomic site where a passage exists across the midline (see Fig. 108-12C).

The lateral aspect of the pararenal space is formed by the ascending and descending colon and their attached dorsal mesenteries. These mesenteries fuse to the anterior aspect of the perirenal fat just lateral to the fusion of the duodenum, and they create a single retromesenteric plane on each side. Laterally, they fuse to the posterolateral fat pads to form the lateroconal plane (Fig. 108-10).

Retroperitoneal Anatomy: Planes

RETROMESENTERIC AND LATEROCONAL PLANES

The lateroconal planes are relatively small. They extend down the length of the ascending and descending colon just lateral to

Figure 108-10 Ruptured renal pelvis. The retromesenteric plane (open arrow), lateroconal plane (solid arrow), and retrorenal plane (curved arrow) contain extraluminal contrast material because of the rupture of the left renal pelvis due to blunt trauma. K, Perinephric space.

the colonic lumen. The retromesenteric planes are major routes by which effusions are distributed in the extraperitoneal abdomen. They are especially important because they are the route of escape for common pathologic entities, such as pancreatitis and colitis. On the left, the retromesenteric plane

Figure 108-11 Superior extent of the interfascial planes: left side. **A.** Blunt dissection of a cadaver prepared as shown in [Figure 108-8A](#). The dissector's hand passes posterior to the pancreas (not shown) and hilum of the spleen (SP) to lie immediately posterior to the stomach (ST) just below its junction with the esophagus (E). The dissector's gloved fingertip (*arrow*) lies on the left crus of the diaphragm (LC) and is covered by the nearly transparent phrenicoesophageal ligament (PEL). **B.** CT shows a section from a clinical case illustrating the superior extent of the interfascial planes. In this patient with pancreatitis, fluid fills the retrorenal plane (RRP) and retromesenteric plane (RMP) surrounding the superior part of the perirenal space (PRS). The collection converges to its most superior location, just lateral to the left crus (LC), posterior and to the left of the esophagus (E), and posterior and to the right of the stomach (ST). This fluid defines the bare area of the stomach. **C.** The CT section was obtained in a patient who had a localized perforation of the tail of the pancreas during an interventional endoscopic procedure. Fluid and gas outline a portion of the retromesenteric plane (RMP) anterior to the perirenal space (PRS) containing the left kidney (LK). The anterior pararenal space is identified by the presence of the proximal descending colon (DC) and its mesenteric fat. TC, Transverse colon; ST, stomach. **D.** The CT section obtained 4 cm superior to that in **C** shows gas in the retromesenteric plane (RMP) adjacent to the left diaphragmatic crus (LC), outlining the bare area of the stomach (*single arrow*) and the bare area (*double arrow*) of the spleen (SP). A, Aorta; ST, stomach.

extends superiorly to abut the left crus of the diaphragm just posterior to the gastroesophageal junction ([Fig. 108-11](#)). On the right, the superior extent is less well understood; clinical observations suggest that the retromesenteric plane on the right (or possibly the superior part of the perirenal space^{44,45}) is directly continuous with the bare area of the liver ([Fig. 108-12](#)).

Inferiorly, the retromesenteric plane is limited and extends over the surface of the kidneys medially as far as the dorsal mesentery. Proceeding inferiorly, this plane becomes

progressively smaller as the perirenal space becomes thinner. Ultimately, it merges with the retrorenal plane below the cone of renal fascia to form the combined plane ([Fig. 108-13](#)).

RETRORENAL PLANE

Superiorly, the retrorenal plane extends to the inferior diaphragmatic fascia. At the level of the kidneys and below, the retrorenal plane typically extends as far medially as the psoas

Figure 108-12 Superior extent of the intrafascial planes: right side. **A.** An oblique fluoroscopic image obtained during an interventional endoscopic procedure shows gas from a duodenal perforation outlining the retromesenteric plane (RMP) anterior to the right kidney (RK). **B.** The chest radiograph obtained immediately after the procedure shows a crescentic gas collection on the medial aspect of the right hemidiaphragm in the location of the bare area of the liver (bal). Gas in the retromesenteric plane (rmp) is discernible superior to the duodenal gas. **C.** CT section obtained in the same patient shows extensive gas filling the superior aspect of the retromesenteric plane (rmp). This gas continues anterior to the inferior vena cava (IVC) and extends to the left between the aorta (A) and superior mesenteric artery (sma) in the part of the retromesenteric plane created by fusion of the mesentery of the duodenum with the great vessels. This allows access of the right-sided plane to its counterpart on the left, anterior to the left kidney (LK) and behind the descending colon (DC). Some of the gas has dissected into the left retrorenal plane (rrp). P, Pancreas; PV, portal vein. **D.** The CT section obtained 4 cm superior to that in **C** shows gas outlining the bare area (bal) of the liver (L). The gas courses around the inferior vena cava (IVC) along the right diaphragmatic crus (rc). Some of the left-sided gas has ascended to the bare area (bas) of the spleen (SP). **E.** The CT section obtained 3 cm superior to that in **D** shows gas outlining the left portion of the bare area (lbal). This gas outlines the left coronary ligament (lcl), the edge of the peritoneal reflection of the left perihepatic spaces. L, Liver; A, aorta.

Figure 108-13 Communication of the intrafascial planes with the pelvis. **A.** Blunt dissection of a cadaver prepared as shown in [Figure 108-8A](#). The descending colon (not shown) is being retracted on its mesentery (DCM), identified by its major vessel, the inferior mesenteric artery (IMA). Just anterior to the anterior renal fascia (ARF) lies the retromesenteric plane (rmp), which extends laterally as far as the colonic mesentery. The perirenal fat (held by the dissector) becomes progressively smaller inferiorly. Posterior to the posterior renal fascia (PRF) is the retrorenal plane (rrp). This plane extends medially as far as the psoas muscle (PM) and ureter (ur). Fluid collections tend to occupy the larger retrorenal plane and extend into the pelvis along the margin of the psoas muscle (PM). **B.** CT shows a section of the inferior aspect of the perirenal space (prs) in a patient with pancreatitis. Fluid in the retromesenteric plane occupies the space immediately behind the descending colon (DC) and its mesentery (DCM), identified here by the inferior mesenteric vein (IMV). Just posterior to the perirenal space and anterior to the psoas muscle (PM) is the retrorenal plane (rrp). It extends medially almost as far as the ureter (ur). Between the ureter and inferior mesenteric vein is the right gonadal vein (gv). The quadratus lumborum muscle (QLM) is identified. **C.** The CT section 15 mm inferior to that in **B** shows no perceptible perirenal fat. The retrorenal and retromesenteric planes have merged to form a combined plane (cp), which occupies the anterolateral surface of the psoas muscle (PM) lateral to the ureter (ur). Notice the extension of the fluid into the lumbar triangle cleft (curved arrow) medial to the posterolateral fat plane (plfp).

muscle (see Fig. 108-13A). In general, retrorenal collections do not extend medial to the ipsilateral ureter. As the retrorenal plane extends inferior to the cone of renal fascia, it joins the retromesenteric plane to become a combined plane that is situated on the anterolateral surface of the psoas muscle, lateral to the ureter and medial to the iliac vessels. It continues into the pelvic extraperitoneum.

PELVIC EXTRAPERITONEAL SPACES AND PLANES

The urinary bladder, along with its embryologically derived attachments, is the central structure in the formation of the pelvic extraperitoneum. The bladder, urachus, obliterated umbilical vessels, and urogenital sinus derivatives are covered by umbilicovesical fascia.⁴⁶ This divides the pelvic extraperitoneum into a small-volume perivesical space and a prevesical space that lies between the perivesical space and the transversalis fascia. In a way analogous to the structure of the perirenal space and fascia, the fascial lining of the prevesical space forms an expandable plane surrounding the bladder. As shown in Figure 108-14, the obliterated umbilical artery (i.e., medial umbilical ligament) contains a variable amount of periligamentous fat and is covered anteriorly and posteriorly by fascia. The anterior fascia forms the umbilicoprevesical plane and passes just posterior to the inferior epigastric artery; laterally, it fuses with the transversalis fascia near the inguinal ring. The posterior fascia forms the umbilicovesical plane and fuses laterally to the combined plane, typically positioned just medial to the obturator fossa. Large collections occupying both of these

Figure 108-14 Fascial planes of the extraperitoneal pelvis. The bladder (BL) occupies the anterior midline and is surrounded by perivesical fascia. Fascia surrounds the triangular fat around the medial umbilical ligaments, containing the obliterated umbilical artery (ua). Posterior to the periligamentous fat is the umbilicovesical fascia (uvf), which blends with the fascial plane around the bladder. Anterior to the fat in the root of the medial umbilical ligament is the umbilicoprevesical fascia (upf), which extends posterior to the inferior epigastric artery (iea). Laterally, this fascia blends with the combined fascial plane medial to the iliopsoas muscle (IPM) and can potentially extend posteromedially, medial to the internal iliac vessels near the piriformis muscle (PYM). Just anterior to the bladder is the obliterated allantois, the urachus (ur), which is surrounded by a variable quantity of fat. The umbilicoprevesical fascia divides in the midline to surround this structure. RM, Rectus muscle; tf, transversalis fascia.

posterior planes straddle the urinary bladder and resemble a molar tooth.

Most fluid collections continue to extend through the prevesical space to involve the transversalis fascia. These can gain access to the combined plane lateral to the colon; from here, they extend posteriorly just medial to the obturator canal to involve the presacral fascia. Moreover, they can gain access to the inguinal canal to extend to the scrotum and to the femoral canal to progress to the lower extremity (Fig. 108-15).

In summary, there exists a complex and voluminous network of fascia capable of transmitting pathologic fluid collections that arise anywhere in the abdomen to locations remote from the original site of the process. This network explains how, for example, pancreatitis can mimic appendicitis or diverticulitis can clinically and radiographically resemble ureteral obstruction. Although fluid from pancreatitis remains the most common pathologic process to involve these planes, cellular spread of aggressive tumors can extend in an identical fashion. A diagrammatic summary of the spaces and planes in the retroperitoneum is shown in Figure 108-16.

Subperitoneal Spaces: Ligaments and Mesenteries

Pathologic fluid collections rapidly seek escape from their space of origin. The interfascial planes are major routes for such escape, but fluid also can extend within the mesentery that originally enfolded the diseased organ. This means of intramesenteric spread is referred to as subperitoneal spread, and it represents extension within the abdominal ligaments.⁴⁷

UPPER ABDOMINAL LIGAMENTS

Most of the mesenteries that persist into adult life as ligaments are present in the upper portion of the abdominal cavity, in part because the ventral mesentery distal to the foregut is resorbed. Described in the following sections are the remnants of the ventral and dorsal mesenteries that supported the gut and the intramesenteric growth of the gut-derived solid viscera: liver, spleen, and pancreas.

Falciform Ligament

The falciform ligament is the remnant of the ventral part of the ventral mesentery. It contains the obliterated umbilical vein, and it is the structure in which large collateral veins are recruited in patients with advanced portal hypertension. It subdivides the peritoneal spaces over the surface of the liver, and it is occasionally a conduit for spread of intrahepatic neoplasms, such as aggressive hepatomas (Fig. 108-17).

Gastrohepatic and Hepatoduodenal Ligaments

The gastrohepatic and hepatoduodenal ligaments are remnants of the dorsal part of the ventral mesentery, between the gut and the liver, and they are known collectively as the lesser omentum. The gastrohepatic ligament extends between the lesser curve of the stomach and the fissure for the ligamentum venosum; it contains the left gastric artery, coronary vein, and part of the hepatic chain of lymph nodes.⁴⁸ It is an important means of spread of gastric cancer into the hilum of the liver, and gastric perforations occasionally extend between its leaves (Fig. 108-18).

Figure 108-15 Retroperitoneal fascial planes. **A.** CT section of a patient with traumatic bladder perforation shows a small amount of urine in the perivesical space (pvs) surrounding the bladder (B). In this patient, there is a larger fat plane than usual around the medial umbilical ligament (mul). There is fluid within the umbilicoprevesical fascia (upvf) anteriorly and the umbilicovesical plane (uvp) posteriorly. On the right, the collection extends posteriorly toward the internal iliac vessels lying on the piriformis muscle (Pym). Anteriorly, the lateral part of the fascia extends posterior to the internal epigastric artery (iea) to blend with the combined plane (cp) near the external iliac vessels (eia and eiv). The iliopsoas muscle (IPM), rectus abdominis muscle (RM), and urachus (ura) are indicated. **B.** CT section in a different patient with a pelvic fracture producing extraperitoneal bladder perforation shows another pattern of fluid distribution in the pelvic extraperitoneum. Contrast material from the bladder has extended into the umbilicoprevesical fascia (upf), which divides in the midline to surround the fat surrounding the median umbilical ligament or urachus (ur). The umbilicoprevesical fascia extends laterally behind the external iliac artery (eia) and enters the transversalis fascia (tf) lateral to the boundary of the rectus abdominis muscle (RM). **C.** CT section obtained 15 mm inferior to that in **B** shows contrast material in the umbilicoprevesical fascia (upf) extending into the combined plane (cp) on the anterior surface of the fat around the medial umbilical ligament (mul). On the right, fluid, but not contrast material, extends posteriorly (arrows) just medial to the iliac vessels and lateral to the perirectal fat as far as the presacral space (PS). **D.** The CT section in another patient with extraperitoneal bladder rupture due to blunt trauma with multiple pelvic fractures shows contrast material from the perforated bladder (B) extending into the umbilicovesical fascia (uvf) and the umbilicoprevesical fascia (upf). On the left, some of this contrast material has entered the combined plane (cp), tracking posteriorly. **E.** A CT section 15 mm inferior to that in **D** shows further accumulation of contrast material in the combined plane (cp).

The hepatoduodenal ligament contains the portal vein, hepatic artery, common hepatic and central cystic ducts, and nodes of the porta hepatis.⁴⁹ At one time, this part of the ventral mesentery contained the ventral pancreas, which later in embryologic development rotated into the retroperitoneum. Pancreatitis recalls that embryologic connection and often extends into the liver through the porta hepatis. Because of this, intrahepatic portal vein thrombosis is a moderately common complication of acute pancreatitis (Fig. 108-19).

Gastrosplenic Ligament, Greater Omentum, and Transverse Mesocolon

The ventral part of the dorsal mesentery extends in the embryo between the greater curvature of the stomach and the spleen. When the right peritoneal cavity extends behind the stomach, this part of the dorsal mesentery is elongated so that a long, redundant surface extends inferiorly. The part of the dorsal mesentery closest to the spleen becomes the adult gastrosplenic ligament, and it can be recognized by the short gastric vessels that course through it. In cases of splenic vein thrombosis, the short gastric veins are routinely recruited as collaterals. A major route of escape for pancreatitis arising in the peripheral body and tail is into the gastrosplenic ligament.⁵⁰ Large intraligamentous collections are frequently mistaken for lesser sac effusions but do not communicate with the peritoneal cavity (Fig. 108-20).

The redundant portion of the gastrosplenic ligament forms two other ligamentous structures in the adult. The inferior portion fuses to form the gastrocolic ligament, or greater omentum. This structure is easily recognized by its contained gastroepiploic vessels, the veins of which dilate in the presence of splenic vein occlusion. The omentum also is the major site of implantation of processes involving the peritoneal cavity. Omental caking from ovarian, endometrial, or gastric primary cancers is commonly recognized (Fig. 108-21).

The posterior and superior part of the redundant gastrosplenic ligament fuses to the anterior leaf of the dorsal mesentery of the transverse colon to form the transverse mesocolon. The middle colic vessels mark the location of this structure; it provides a pathway for escape of pancreatitis that involves the midportion of the pancreas. Greater curvature gastric ulcers, benign or malignant, course down the transverse mesocolon to create gastrocolic fistulas (Fig. 108-22). The transverse mesocolon is also an important pathway of direct spread from tumors arising from the nearby pancreas.^{51,52}

Splenorenal Ligament

The tail of the pancreas arises in the splenorenal ligament. When the right peritoneal cavity creates the lesser sac, it also rotates the pancreas and the ligament clockwise, and they become part of the retroperitoneum. Effusions in the splenorenal ligament are difficult to distinguish from fluid in the anterior pararenal compartment.

Root of the Intestinal Mesentery

The small bowel mesentery is a broad fold of peritoneum connecting the intestine to the posterior abdominal wall just anterior to the great vessel space.^{53,54} It is recognized by the superior mesenteric artery and its branches and by the superior mesenteric vein and its tributaries. Mesenteric lymph nodes are readily observed on cross-sectional imaging. Pancreatitis occasionally extends into the root of the mesentery, but the mesentery is most commonly seen in patients with ascites, which outlines the mesenteric pleats.

LOWER ABDOMINAL LIGAMENTS

The sigmoid mesocolon contains the sigmoid and hemorrhoidal branches of the inferior mesenteric artery and the large inferior mesenteric vein, which can be traced to its junction

Figure 108-16 Collection in the retrorenal plane extending from the pelvis to the diaphragm. **A.** CT section at the level of the inferior left hemidiaphragm shows a collection in the retrorenal plane (RRP) extending lateral to the psoas muscle (PM) behind the fat in the perirenal space (PRS) and left kidney (LK), to the left of the spleen (SP). **B.** A CT section inferior to that in **A** shows the collection in the retrorenal plane (RRP), which has expanded into the posterolateral fat pad (PLF). There is extension of the collection into the superior extent of the lateroconal plane (LCP). Also note the collection along the transversalis fascia (TF). **C.** Inferior to section **B**, collections in the lateroconal plane and along the transversalis fascia have merged into one collection containing a drainage catheter (arrow).

Figure 108-16, cont'd **D.** The CT section at the level of the true pelvic inlet shows the collection in the combined plane (CP), anterior to the iliopsoas muscle (IPM), extending between the sigmoid colon (SC) and its mesentery (SCM) and the iliac vessels (EIA), communicating with an extraperitoneal collection surrounding the rectum, the cranial portion of which is noted on this section (arrow). (Case courtesy Doug Kitchin, MD.) **E.** CT section from the same patient at the level of the acetabula shows collections extending medially into the extraperitoneal perirectal space (PS) surrounding the rectum (R). **F.** A sagittal reformatted image in the same patient shows the continuity of the retrorenal plane (RRP) extending from the left hemidiaphragm behind the perirenal space (prs) through the combined plane (cp) into the pelvic extraperitoneum. **G.** The line drawing depicts a sagittal view summarizing the retroperitoneal spaces and planes. Encircling the abdomen, the transversalis fascia (TF) provides an expandable plane available to fluid collections from any source. Internal to the transversalis fascia are the posterolateral fat pads (PLFP), or posterior pararenal spaces, which contain no viscera and rarely participate in pathologic processes. Internal to the posterior pararenal spaces are the perirenal spaces (PRS) surrounding the kidney (K) and adrenal glands. On the right, the perirenal space appears to be open to the bare area of the liver (dashed arrow). The boundary between the posterior pararenal and perirenal spaces creates an expandable plane, the retrorenal plane (RRP). Anterior to the perirenal spaces are the organs and mesenteries that compose the anterior pararenal space (APS). The boundary between these two spaces creates the retromesenteric plane (RMP). Below the cone of renal fascia, the retrorenal and retromesenteric spaces join to form the combined plane (CP) that extends to the pelvic extraperitoneum. BAL, bare area of the liver; D, duodenum; L, liver; P, pancreas.

Figure 108-17 Falciform ligament. The falciform ligament (fl) is outlined by ascites in this patient with hepatic failure. There is fluid in the left anterior perihepatic space (laps) and in the right subphrenic space (RSPS), which are separated by a remnant of the ventral mesentery, the falciform ligament. L, Liver; LPSS, left posterior subphrenic space; ST, stomach.

Figure 108-18 The gastrohepatic ligament. Gastric cancer has produced an extensive lobular mass (M) that extends from the stomach (ST) to the gastrohepatic ligament (GHL), which is identified by the left gastric artery (LGA). A, Aorta; IVC, inferior vena cava; RK, right kidney; PV, portal vein; SP, spleen.

Figure 108-19 Embryologic explanation of subperitoneal spread from the pancreas to the liver hilum. **A.** Line drawing of an embryo during early development shows the intramesenteric development of the ventral pancreas (VP) in the ventral portion of the mesentery, which contains the developing liver (cephalic to this image). This mesentery ultimately becomes the hepatoduodenal ligament (HDL) in the adult. As the fetus develops, the ventral pancreas rotates in the direction of the arrow, along with the duodenum (D), to fuse with the dorsal pancreas (DP). LK, Left kidney; RK, right kidney; SRL, splenohepatic ligament. **B.** Somewhat later, the ventral pancreas (VP) is still attached to its mesentery (HDL) and is fused to the right side of the dorsal pancreas (DP). As the fetus develops further, both parts of the pancreas and the duodenum rotate in the direction of the arrow to fuse with the posterior surface of the retroperitoneum just anterior to the right kidney (RK). A, Aorta. **C.** After all rotations, a line drawing shows that the ventral pancreas (VP), now a part of the anterior pararenal space, retains its connection to the liver (L) through the HDL. **D.** Clinical case of pancreatitis shows extension of pancreatic fluid along the HDL into the hilum of the liver anterior to the portal vein (PV) as well as into the more superior gastrohepatic ligament (GHL). IVC, inferior vena cava.

Figure 108-20 Subperitoneal spread into the gastrosplenic ligament. **A.** Line drawing of the ligaments in the upper abdomen shows the stomach (ST) attached through the ventral mesentery to the liver (L); this becomes the lesser omentum (LO) in the adult. The ventral part of the dorsal mesentery is called the gastrosplenic ligament (GSL), and it connects the greater curvature of the stomach to the spleen (SP). Its redundant inferior folds become the greater omentum (GO). The pancreas (P) lies in the dorsal part of the dorsal mesentery, most of which fuses to the dorsal body wall to become the splenorenal ligament (SRL). Effusions arising in the pancreatic tail can extend to any part of the dorsal mesentery. **B.** CT section in a patient with pancreatitis shows extension of the fluid collection into the gastrosplenic ligament (GSL), identified by the short gastric arteries (arrows) above the spleen (SP). A portion of this collection extends along the greater curvature of the stomach (ST). **C.** CT section in another patient with pancreatitis shows a large fluid collection within the gastrosplenic ligament (GSL) distorting the greater curvature of the stomach (ST). This collection is frequently misidentified as being in the lesser peritoneal sac. The spleen (SP) is identified on the right.

Figure 108-21 The greater omentum. **A.** CT section through the upper part of the pelvis in a patient with widespread peritoneal metastases from an ovarian primary shows extensive soft tissue deposits in the greater omentum (go) in its characteristic location in the anterior abdomen. There are also deposits in the sigmoid mesocolon (smc) adjacent to the sigmoid colon (SC) just anterolateral to the uterus (U). **B.** CT section through the upper abdomen in a patient with gastric perforation into the greater and lesser peritoneal sacs shows contrast material within the lumen of the stomach (ST) that has leaked into the left peritoneal spaces to occupy the left anterior perihepatic space (LAP) and left posterior perihepatic space (LPP) on the surface of the left lobe of the liver (L). There is also contrast material in the left posterior subphrenic (or perisplenic) space (lps) above the spleen (SP). Some dense contrast material has leaked into a space between the leaves of the greater omentum, filling the omental bursa (OB), part of the inferior recess of the lesser sac. **C.** CT section 15 mm inferior to that in B shows the communication between the inferior recess of the lesser sac (IR) and the contrast material collection within the greater omentum (OB). The right subphrenic space (RSS) is identified on the left. LAPS, Left anterior perihepatic space.

Figure 108-22 The transverse mesocolon. **A.** Coronal reformat image in a patient with voluminous ascites shows the transverse mesocolon (TMC), identified by the middle colic vein (mcv), which subdivides the peritoneal spaces into supramesocolic and inframesocolic compartments. A zone of continuity is located centrally between the transverse mesocolon and the root of the small bowel mesentery (marked by the superior mesenteric vessels [sma and smv]). There is ascitic fluid in the right subphrenic (rs) and hepatorenal (hr) spaces in the right supramesocolic peritoneum; some fluid is also seen within the inferior recess of the lesser sac (lr). Fluid in the left anterior subphrenic space (las) outlines the greater omentum (go) and the phrenicocolic ligament (pcl) and communicates with the left paracolic gutter (LPG) in the inframesocolic peritoneum. Fluid in the pelvic portion of the inframesocolic space outlines segments of the descending colon (DC) and sigmoid colon (SC) and the fat-rich sigmoid mesocolon (smc). L, Liver. **B.** CT section illustrates extension of pancreatitis to the transverse mesocolon (tmc). The fluid collection (F) extends along the middle colic vein (mcv) to lie within the leaves of the transverse mesocolon. The transverse colon (tc) and pancreatic head (P) are identified. **C.** Coronal reformat image in a patient with colon cancer shows extension of the primary tumor in the transverse colon (tc) through the transverse mesocolon (tmc) into the stomach (ST). **D.** Sagittal view of the same patient as in **C** shows the fistula (arrow) between the transverse colon (tc) and the stomach (ST) by means of the transverse mesocolon (tmc).

with the splenic vein. Processes that begin in the sigmoid colon, such as diverticulitis, seep through the porous mesentery to distend the combined interfascial plane. The sigmoid mesentery is also one of the common locations for peritoneal seeding in gynecologic primary carcinomas.

Peritoneal Spaces: Upper Abdomen

The peritoneal cavity consists of a series of communicating but compartmentalized potential spaces that are not depicted on conventional radiologic studies or by cross-sectional imaging

unless they are distended by fluid or air. The lining of the peritoneal cavity and of the abdominal and pelvic organs contained therein is a mesothelial surface known as peritoneum. Peritoneal spaces are bounded by extensions of the ventral and dorsal mesentery, the ligaments (Fig. 108-23). The abdominal cavity is subdivided to some extent by the largest of these ligaments, the transverse mesocolon, which forms an upper (supramesocolic) and a lower (inframesocolic) compartment.⁵⁵ In the supramesocolic compartment, the gut and its mesenteries effectively prevent communication between the right side of the peritoneal space and the left.

Figure 108-23 Supramesocolic peritoneal spaces. **A.** Line drawing of the supramesocolic peritoneal spaces shows the falciform ligament (fl) delimiting the right side of the left anterior perihepatic space (lap), formed when the lateral segment of the liver (L) grew to the left and distorted the peritoneum around it. The left posterior perihepatic space (lpp) is always parallel to the lesser curvature of the stomach (ST), and it is limited posteriorly and on the right by the gastrohepatic ligament (ghl). Between the stomach and the diaphragm lies the left anterior subphrenic space (las), which extends posteriorly to surround the spleen (SP) in the left posterior subphrenic space (lps). On the right, the right subphrenic space courses between the liver and right hemidiaphragm between the falciform ligament and the bare area of the liver (bal). The caudate lobe grows into the superior recess of the lesser sac (srls), deforming it into its characteristic boomerang shape. Posterior to the stomach lies the inferior recess of the lesser sac (irls). rsls, Right subphrenic space. **B.** CT section similar in location to that in **A** in a patient with voluminous ascites shows the falciform ligament (fl) outlined by a large collection in the left anterior perihepatic space (LAP). There is only a tiny fluid collection in the left posterior perihepatic space (LPP), but ascites fills the left anterior subphrenic (LAS) and left posterior subphrenic (LPS) spaces. On the right, the liver surface is distorted by the tense collection in the right subphrenic space (rs), and there is a large volume of fluid in the hepatorenal (hr) space. A small volume of fluid is present in the superior recess of the lesser sac (srls). Notice the thin gastrohepatic ligament (arrow) separating the left posterior perihepatic space from the superior recess. SP, Spleen; ST, stomach.

Figure 108-24 Left perihepatic spaces. **A.** Coronal reformatted image in a patient with ascites shows fluid surrounding the lateral segment of the liver (L) in the left anterior (LAP) and posterior (LPP) perihepatic spaces. Fluid in the left anterior subphrenic space (LAS) outlines the gastrocolic ligament, or greater omentum (GO). The left-most extension of the transverse mesocolon attaches to the left hemidiaphragm to form the phrenicocolic ligament (PCL), which forms an incomplete barrier between the supramesocolic and inframesocolic portions of the peritoneum. The stomach (ST) and inferior recess of the lesser sac (IRLS) are identified, as is the spleen (SP). **B.** CT section in a patient with widespread calcified mucinous tumor implants throughout the peritoneum shows the intrahepatic extent of the left posterior perihepatic space (LPP). Metastases occur over the diaphragmatic surface of the right lobe in the right subphrenic space (RS). Also noted is the transverse mesocolon.

LEFT-SIDED PERITONEAL SPACES

In the following discussion, the peritoneal spaces are arbitrarily divided into a number of subspaces. Although left-sided spaces can communicate freely, clinically observed pathologic fluid collections frequently occupy one or more of the subcompartments, separated by fibrous adhesions.

Perihepatic Space

Two left perihepatic spaces are formed as the left lateral segment of the liver grows into and distorts the left peritoneal cavity.

The anterior left perihepatic space extends over the surface of the liver, limited on the right by the falciform ligament. The posterior left perihepatic space (or gastrohepatic recess⁵⁶) extends between the lesser curvature of the stomach anterior to the gastrohepatic ligament and posterior to the left lobe of the liver. It can extend deeply into the liver parenchyma along Glisson's capsule, and peritoneal processes can mimic primary intrahepatic disease. Fluid in the gastrohepatic recess is immediately anterior to fluid in the superior recess of the lesser sac (Fig. 108-24).

Subphrenic Space

Immediately to the left of the perihepatic space is the anterior subphrenic space,⁵⁷ which is bounded by the diaphragm anteriorly and laterally and by the stomach posteriorly. Lateral to the stomach, the anterior subphrenic space communicates with the posterior subphrenic (or perisplenic) space. The perisplenic space almost completely surrounds the spleen,⁵⁸ except for a variable portion of splenic tissue lying within the splenorenal ligament. This bare area of the spleen prevents fluid from tracking medially at the level of the splenic hilum.⁵⁹ Inferior to the tip of the spleen, the attachment of the left side of the transverse mesocolon to the left hemidiaphragm creates the phrenocolic ligament, which almost completely effaces the posterior subphrenic compartment. It forms a relative barrier to fluid extension up the left paracolic gutter into the supramesocolic compartments.⁶⁰

RIGHT-SIDED PERITONEAL SPACES

Supramesocolic spaces on the right side of the abdomen are most influenced by the liver. A portion of the right peritoneal cavity, however, crosses behind the stomach through the epiploic foramen (or foramen of Winslow) and comes to lie to the left of the midline.

Subdiaphragmatic Space

The right subdiaphragmatic space is limited anteriorly by the falciform ligament and posteriorly by the hepatic bare area, which is broadest just below the junction of the inferior vena cava with the right atrium.⁶¹ Collections in this space frequently deform the surface of the liver (Fig. 108-25). Of note, subhepatic and subphrenic abscesses on the right side of the abdomen occur with a greater frequency than those on the left side owing to a shallower left paracolic gutter compared with its right-sided counterpart as well as flow limited by the phrenocolic ligament.⁶²

Hepatorenal Space

Just beneath the bare area, the right peritoneal space courses between the posterior surface of segment VI and the anterior renal fascia on its way to the epiploic foramen. This relatively small potential space is referred to as the hepatorenal fossa or, more commonly, Morison's pouch. Collections frequently form here in patients recovering from upper abdominal surgery (often cholecystectomy) because it is the most dependent portion of the right supramesocolic spaces.

Lesser Sac

There are two components to the lesser sac (i.e., omental bursa), the name applied to the portion of the right peritoneal space that passes posterior to the gastrohepatic omentum and stomach.⁶³⁻⁶⁵ The caudate lobe of the liver distorts the right side of the peritoneum to form a boomerang-shaped superior recess (Fig. 108-26). The larger inferior recess is bounded anteriorly by the stomach, posteriorly by the anterior pararenal space, and inferiorly and to the left by the transverse mesocolon. The inferior recess communicates with a potential space lying inside the leaves of the greater omentum (Fig. 108-27). Although fluid in the lesser sac is most commonly caused by generalized peritoneal fluid entering through the epiploic foramen, inflammation from pancreatitis, cholecystitis, or gastric perforation may cause ascites localized to the lesser sac.⁶⁶

Peritoneal Spaces: Lower Abdomen and Pelvis

INFRAMESOCOLIC SPACE

The inframesocolic compartment is divided into two unequal spaces by the small intestinal mesentery. The smaller right inframesocolic space is restricted inferiorly by the junction of the distal small bowel mesentery with the cecum, whereas the larger left inframesocolic space opens into the pelvis,

Figure 108-25 Right perihepatic spaces. A. Coronal reformatted image in a patient with ascites shows fluid between the right hemidiaphragm and the liver (L) in the right subphrenic space (RS). This is continuous with fluid in the hepatorenal recess (HR) on the inferior surface of the liver, superior to the right kidney (RK) and fat in the perirenal space (PRS). The hepatorenal space is also called Morison's pouch. **B.** Sagittal reformatted image in another patient shows the continuity between the right subphrenic space (rs) and Morison's pouch (HR), which extends between the liver (L) and the right kidney (RK). Notice the posterior location of the bare area of the liver (BAL), in which no ascites is present.

Figure 108-26 The foramen of Winslow. **A.** In a patient with peritoneal bladder perforation from trauma, CT shows contrast material from CT cystography filling the right subphrenic space (RS) around the liver (L) and flowing into the hepatorenal recess (HR) between the liver and the perirenal space (PRS). Some of this contrast material has extended into the two compartments of the lesser sac. The denser collection lies within the superior recess of the lesser sac (SRLS), surrounding the caudate lobe (CL), and the more dilute collection is in the inferior recess of the lesser sac (IRLS), posterior to the stomach (ST). **B.** CT section 15 mm inferior to that in **A** shows hepatorenal recess fluid (HR) funneling into the superior recess of the lesser sac (SRLS) through the narrow foramen of Winslow (FW), which lies between the inferior vena cava (IVC) and the portal vein (PV). The aorta (A), caudate lobe (CL), and inferior recess of the lesser sac (IRLS) are identified. **C.** CT section in another patient who proved to have a perforated gastric ulcer shows dense contrast material leaking from the lumen of the stomach (ST) into the superior recess of the lesser sac (SRLS), defining its characteristic boomerang shape on the medial surface of the caudate lobe (CL). The liver (L) is identified. **D.** CT section in a patient with ascites shows the relationship between the collection in the left posterior perihepatic space (LPP) and the smaller collection in the superior recess of the lesser sac (SRLS). Between the two collections lies the gastrohepatic ligament (arrows). The aorta (A), liver (L), stomach (ST), and spleen (SP) as well as a tense collection in the left anterior perihepatic space (LAP) also are identified.

Figure 108-27 Boundaries of the inferior recess of the lesser sac. **A.** Oblique coronal reformatted image in a patient with ascites shows the inferior recess of the lesser sac (irls) bounded by the stomach (ST) superiorly, the gastrocolic ligament (gcl) on the left, and the transverse mesocolon (tmc) inferiorly. On the right, it is open to the superior recess of the lesser sac (srls), which empties into the hepatorenal recess (hr). The left anterior subphrenic space (las) and left paracolic gutter (lpg) also are identified. **B.** Sagittal reformatted image in the same patient shows the inferior recess of the lesser sac (irls) bounded superiorly by the stomach (ST), posteriorly by the splenorenal ligament (srl), and inferiorly by the transverse mesocolon (tmc). L, Liver; lap, left anterior perihepatic space; LK, left kidney; P, pancreas; SP, spleen; TC, transverse colon.

Figure 108-28 Intraperitoneal flow of ascites. The inframesocolic compartment is divided by the small bowel mesentery. The smaller right infracolic space (RIS) is restricted inferiorly by the junction of the distal small bowel mesentery with the cecum. Except where it is bounded by the sigmoid mesocolon, the larger left infracolic space (LIS) opens into the pelvis. The paracolic gutters are located lateral to the peritoneal reflections of the ascending colon (AC) and descending colon (DC). The right paracolic gutter freely communicates with the right supramesocolic spaces. The phrenicocolic ligament (PCL) forms a partial barrier between the left paracolic gutter and the left subphrenic space. L, Liver; TC, transverse colon.

except where it is bounded by the sigmoid mesocolon (Fig. 108-28). The paracolic gutters are located lateral to the peritoneal reflections of the ascending and descending colon. The right paracolic gutter freely communicates with the right supramesocolic spaces, and the phrenicocolic ligament forms a partial barrier between the left paracolic gutter and the left subphrenic space.

Figure 108-29 The pelvic peritoneum. The pelvic peritoneal spaces are depicted in a male patient with ascites. The large, medially positioned supravesical fossa (svf) is crossed on both sides by the medial umbilical ligaments (mul), which separate it from the inguinal spaces. The inguinal spaces are divided by the lateral umbilical fold, which contains the inferior epigastric artery (iea), into medial (mif) and lateral (lif) compartments. In women, the uterus separates the posteriorly located rectovesical pouch (rvf), also known as the pouch of Douglas, from the supravesical fossa. The urachus (ur) is identified.

PELVIC PERITONEAL SPACES

The most dependent portion of the peritoneal space in supine and erect positions is in the pelvis, and this anatomic feature explains the frequency of abscesses and peritoneal implantation of tumor in this region. In males, this cul-de-sac lies between the anterior mesorectal fascia and the posterior wall of the bladder. In females, the equivalent space lies between the uterine wall and the anterior mesorectal fascia.⁶⁷ Anteriorly, the pelvic peritoneum is indented by two folds. The medial umbilical folds, which contain the obliterated umbilical arteries, divide the peritoneum into medial and lateral compartments, and the inferior epigastric arteries divide the lateral compartment into medial and lateral inguinal fossae (Fig. 108-29).

Abdominal Wall Route

Conclusions

Traditionally, the abdominal cavity has been divided into a number of peritoneal, retroperitoneal, and extraperitoneal spaces.¹ Although it is useful for learning abdominal anatomy and appreciating the confinement of disease in a particular space, this classic approach affords limited understanding of

the intra-abdominal spread of disease. Dissemination of disease between the retroperitoneum and the peritoneal cavity, between the subdivisions of the retroperitoneum, and within the subperitoneal spaces is difficult to conceptualize if the various spaces and compartments of the abdomen and pelvis are considered fixed, immutable, and isolated delineators of anatomy. Meyers and colleagues perceived that the abdominal cavity should be viewed rather as a continuous space that is punctuated by the abdominal mesenteries, ligaments, and fascia, which may confine disease or provide an avenue for its spread.²⁻⁷ Blood vessels, lymphatics, and the biliary system also contribute to the spread of a number of benign and malignant processes. This holistic schema provides a rationale for understanding the dissemination of intra-abdominal disease focally and to areas distant from the site of origin.

Hematogenous Spread

MALIGNANT DISEASE

Malignant neoplasms shed as many as 4 million cells per gram of tumor tissue into the bloodstream every day. Of these cells, more than 90% are cleared rapidly from the circulation.^{8,9} Despite this metastatic inefficiency, the abdominal organs and gut (Fig. 109-1) are common sites of hematogenous metastases from intra-abdominal and extra-abdominal primary sites.^{8,9}

Liver Metastases

Because of its dual blood supply, the liver is a common site of metastatic disease.¹⁰ The portal system conveys cancer cells from tumors of the colon, pancreas, stomach, and small bowel, whereas the systemic arterial system carries metastases from any site but most often from the lung and breast. The liver is particularly vulnerable to the deposition of metastases because of its architecture. Kupffer cells extend into the hepatic sinusoids and impede the passage of tumor cells. These cells then subendothelially extravasate, indent the hepatocytes, and, because of their position adjacent to the sinusoids, receive a rich mixture of arterial and portal blood.¹¹⁻¹³ In this favorable milieu, it is not surprising that metastases in the liver grow four to six times faster than those at other sites, that the liver is the second most common site of metastases (after lymph nodes), and that 25% of all patients who die of cancer have liver metastases.¹²

The radiographic appearance of liver metastases depends on the tumor type, its vascularity, and the degree to which neovascularization occurs. Well-established metastases derive most of their blood supply from the hepatic artery, and this fact is important for planning local hepatic chemotherapy or embolization therapy.¹⁰

Figure 109-1 Hematogenous metastases: imaging spectrum.

A. Contrast-enhanced MR scan shows multiple hepatic metastases from a small bowel neuroendocrine tumor. **B.** PET scan in a different patient shows multiple hepatic metastases from a small bowel adenocarcinoma.

Gut Metastases

The hollow viscera are important but less frequent sites of hematogenous metastases. Carcinoma of the breast or lung and melanoma are the most common primary tumors. On occasion, symptoms of bowel metastases, such as obstruction or hemorrhage, may be the initial clinical manifestations of an occult primary neoplasm.¹⁴

The radiographic appearance of gut metastases depends on the primary tumor type, the degree of vascularity and rate of growth, and the tumor's ability to induce desmoplasia. Hematogenous metastases have a distinct predilection for the antimesenteric border of the bowel¹⁴ because tumor cells are trapped in the smallest capillaries, which are located on the antimesenteric side of the gut.¹⁵ The mesenteric vessels are larger at their entrance on the mesenteric border.¹⁶ A mass, ulcer, ulcerated mass, or area of stenosis may be seen radiographically.

INFECTION

Portal Vein

In the preantibiotic era, pyogenic liver abscesses were usually caused by portal vein pyemia resulting from appendicitis, diverticulitis, or pelvic inflammatory disease.¹⁷ In Western countries, portal vein pylephlebitis is now rare, and ascending biliary infections are the most common cause of pyogenic hepatic abscesses.¹⁸⁻²⁰

Approximately 10% of the world's population are infected by *Entamoeba histolytica*, and 10% of these infections cause clinical disease. The portal vein remains the principal conduit for invasive amebiasis of the colon. The protozoa gain access to the portal venous system by invading the colonic mucosa, and they are then carried to the liver, where they obstruct small portal and arterial radicles, producing parenchymal infarction and proteolysis with subsequent abscess formation.²¹

The portal vein also transmits the eggs of *Echinococcus granulosus* to the liver. The eggs are dissolved by the digestive juices, and the released oncospheres pass through the duodenal mucosa into the portal circulation. In the liver, the eggs disintegrate or grow into a hydatid cyst (see Chapter 88).^{21,22}

Schistosoma mansoni organisms are also carried to the liver through the portal vein. When the worm burden is sufficient, portal vein obstruction may occur, leading to portal hypertension. Schistosomiasis is the most common cause of portal hypertension in the world.^{21,22}

Systemic Arteries

Before the 1980s, hematogenous dissemination of bacterial infections to the abdomen was becoming less frequent and less lethal. This pathway, however, is making a grim comeback in injection drug users, patients with acquired immunodeficiency syndrome (AIDS), and other immunocompromised persons.²³ Pyogenic and nonpyogenic abscesses (as found in candidiasis, tuberculosis, and *Pneumocystis jiroveci* and *Cryptococcus neoformans* infections) occur with greater frequency in these patients.²⁴⁻²⁸

Lymphatic Spread

Neoplasms of the bile ducts, pancreas, stomach, small bowel, and colon (Fig. 109-2) commonly invade adjacent lymphatics. Although a specific discussion of each malignant neoplasm is beyond the scope of this chapter, several fundamental principles apply. Lymphatic tumor emboli from primary bowel neoplasms are not always arrested in the nearest draining lymph node. Lymphatic obstruction of a more remote node may occur because of cellular impaction. This can cause retrograde tumor spread to an adjacent segment of gut or a more distant portion of the alimentary tract. This may explain the phenomenon of anastomotic recurrence of colon cancer, even though a no-touch technique and wide surgical margins are used during resection.²⁹

Tumor-induced derangements of lymph flow produce a number of radiographic findings. In the colon, there may be edema of the bowel wall with mucosal thickening, loss of colonic haustra, and narrowing of the lumen. On computed tomography (CT) scans, increased attenuation of the pericolic fat may be seen.³⁰ With disease progression, nodular tumor deposits accompany the edema, leading to thumbprinting in the

Figure 109-2 Lymphatic metastases: CT findings. **A.** Large necrotic carcinoma of the ascending colon with malignant ascites and retroperitoneal adenopathy. **B.** Sagittal reformatted image shows metastatic lymphadenopathy (arrows) within the small bowel mesentery.

colon and cobblestoning of the small bowel. These radiographic findings, which may simulate ischemic colitis and Crohn's disease, respectively, indicate extensive lymphatic permeation and suggest that resection will probably not be curative.⁶ Lymphatic obstruction by tumor at the root of the small bowel mesentery may cause focal or diffuse thickening of the valvulae conniventes from lymphedema or tumor infiltration. When the lymphatics of the liver are obstructed, periportal lymphedema develops, which may cause zones of periportal lucency on CT scans and periportal hyperintensity on T2-weighted magnetic resonance (MR) images of the liver.³¹

Infection and inflammatory disease can also be spread through lymphatics. Patients with viral hepatitis often show spread of the hepatic inflammatory process to regional lymph nodes (see Chapter 89).³²⁻³⁴

Biliary Spread

INFECTION

The biliary system is a major conduit for infectious disease.³⁵ Asian cholangiohepatitis is the most common biliary tract disease in parts of China, Japan, and other countries of the Far East. Most affected persons harbor parasites of *Clonorchis sinensis* or *Fasciola hepatica*, which may obstruct the bile ducts or act as a nidus for stone formation and chronic inflammation. These liver flukes migrate from the duodenum, through the ampulla of Vater, and on to any part of the biliary tract.³⁶⁻³⁸

Ascaris lumbricoides affects one fourth of the world's population. Adult worms often migrate from the duodenum through the ampulla of Vater to lodge in the gallbladder, the biliary tract, or less commonly the pancreatic duct. Patients may present with acute cholecystitis or biliary obstruction.³⁸⁻⁴² Established liver infections, such as hydatid cysts, may erode through and rupture into the biliary system, and the expelled contents may cause obstructive jaundice (see Chapter 88).⁴³

Ascending cholangitis is a pyogenic infection of the biliary tract and the most common cause of liver abscess in the Western world. It occurs in the clinical setting of obstruction

and biliary stasis proximal to an obstructing stone, stricture, or neoplasm.²⁰

Patients with AIDS are subject to a number of biliary and pancreatic duct abnormalities because of direct involvement by organisms such as *Cryptococcus* and *Cryptosporidium*, which also migrate from the duodenum through the ampulla. On radiographic evaluation, infection may produce an appearance similar to that of sclerosing cholangitis, papillary stenosis, or acute cholecystitis (see Chapter 80).⁴³⁻⁴⁹

MALIGNANT DISEASE

Hepatocellular carcinoma and cholangiocarcinoma uncommonly seed the biliary tract.^{42,50}

Peritoneal Spread

INTRAPERITONEAL FLOW OF FLUID

The peritoneal cavity contains a number of compartmentalized but communicating spaces (see Chapter 108). The peritoneal cavity can be divided into supramesocolic and inframesocolic spaces by the transverse mesocolon. Four intraperitoneal spaces are present in the supramesocolic portion of the abdomen: the suprahepatic and subhepatic spaces on the right and the subphrenic space and lesser sac on the left. The inframesocolic portion of the peritoneal cavity is divided into the right and left inframesocolic spaces by the small bowel mesentery. The large left inframesocolic space is open to the pelvis, except where it is bounded by the sigmoid mesocolon. The right inframesocolic space is smaller and caudally restricted by the junction of the distal small bowel mesentery with the cecum. The most dependent portions of the peritoneal cavity are the lateral paravesical spaces and the pouch of Douglas (i.e., cul-de-sac in women and rectovesical space in men). The pelvis communicates with the supramesocolic space through the paracolic gutters, which lie lateral to the attachments of the peritoneal reflections of the ascending and descending colon. The right paracolic gutter is continuous with the right subhepatic and suprahepatic space

and diaphragm. On the left, the phrenicocolic ligament forms a partial barrier between the left paracolic gutter and the left subphrenic space.⁵¹⁻⁵⁴

The natural flow of intraperitoneal fluid occurs along pathways determined by the anatomic compartmentalization of the peritoneal cavity, intraperitoneal pressure, position of the patient, site of fluid origin, nature of fluid, speed of fluid accumulation, presence of adhesions or previous surgery, degree of bladder distention, and density of fluid (Fig. 109-3).^{5,6,54-58} Abscesses form and malignant cells grow where natural flow allows the affected ascitic fluid to pool. Fluid in the inframesocolic space seeks the pelvis but may first seed the superior aspect of the sigmoid colon on the left and the medial aspect of the cecum on the right. In the pelvis, infected and malignant fluid fills the pouch of Douglas and then the lateral paravesical recesses. Pelvic fluid then ascends both paracolic gutters, driven by negative intra-abdominal pressure associated with respiration, volume considerations, and topographic anatomy of peritoneal recesses.^{5,54} The flow in the left paracolic gutter is modest and limited by the phrenicocolic ligament. Most flow occurs in the right paracolic space. Fluid in this gutter has access to Morison's pouch (the hepatorenal recess of the subhepatic space), the right subphrenic space, and potentially the lesser sac through the anterior subhepatic space and foramen of Winslow. The falciform ligament usually prevents fluid spread across the midline from the right to the left subphrenic spaces.⁵¹⁻⁵⁸

The most common sites of intraperitoneal abscess are the pelvis, the right subhepatic space, and the right subphrenic space. Similarly, the pouch of Douglas, the lower small bowel mesentery near the ileocecal junction, the sigmoid mesocolon, the right paracolic gutter, and the right subhepatic and subphrenic spaces are the most common sites for the growth of seeded peritoneal metastases.^{6,15,50-58}

POUCH OF DOUGLAS

Malignant Disease

The pouch of Douglas projects at the level of the lower second to fourth sacral segment in most people (Fig. 109-4). On barium studies, drop metastases to this pouch produce a nodular, serosal indentation or fixed parallel folds along the anterior aspect of the rectosigmoid junction. These changes, which clinically correlate with the classic Blumer shelf, reflect the coalescence of tumor deposits with a dense fibrous reaction. This radiographic appearance can be simulated by endometriosis, inflammation of the seminal vesicles, prostate neoplasm or infection, scirrhous colon cancer, or radiation-induced changes.^{5,6}

Infection

Infected fluid naturally pools in the pouch of Douglas, often leading to abscess formation (Fig. 109-5). On plain radiographs, this fluid may be seen as a soft tissue density superior to the urinary bladder. Abscesses may also cause extrinsic distortion of the bladder dome, compress the rectosigmoid junction, or posteriorly and superiorly displace the sigmoid colon.⁵⁻⁷

PERIHEPATIC SPACES

Malignant Disease

Perihepatic dissemination of ovarian carcinoma is commonly seen on CT scans and is manifested as nodular, plaque-like, or

sheetlike masses that may be calcified (Fig. 109-6). Free-floating ovarian carcinoma cells are removed from the peritoneum by lymphatic channels in the diaphragm, particularly on the right. The submesothelial lymphatic capillaries of the diaphragm penetrate the muscle to communicate with a similar plexus arising on the pleural surface. From these diaphragmatic lymphatics, lymph drains to the cardiophrenic and mediastinal lymph nodes. Accordingly, a pelvic malignant neoplasm such as ovarian carcinoma can cause adenopathy at the cardiophrenic angle. Malignant ascites and peritoneal implants occur when these lymphatics are obstructed by tumor.^{6,59}

Infection

Right subphrenic and subhepatic abscesses occur two to three times more frequently than left subphrenic and perisplenic abscesses because of the fact that more right-sided surgical procedures, such as cholecystectomy and appendectomy, are performed and because Morison's pouch acts as a sewer for the right paracolic gutter. Infected fluid on the right side does not extend to the left subphrenic space because it is blocked by the falciform ligament.^{5,60-62}

LEFT SUBPHRENIC SPACE

Left subphrenic space (Fig. 109-7) abscesses most commonly result from perforated anterior gastric or duodenal bulb ulcers or are a sequela of gastric, colonic, or splenic surgery. The negative intra-abdominal pressure beneath the diaphragm preferentially draws infected material toward the diaphragm. The phrenicocolic ligament and falciform ligament prevent transcoelomic spread of generalized peritonitis and tumor.^{5,6,61}

LOWER SMALL BOWEL MESENTERY

A series of peritoneal recesses is formed along the right side of the small bowel mesentery as the mesenteric ruffles extend from the root of the mesentery to support the small bowel loops. Disease-bearing fluid and cells cascade from recess to recess toward the right lower quadrant and pool at the level of the distal ileum and cecum before overflowing into the pelvis.^{15,63}

Malignant seeding down the small bowel mesentery (Fig. 109-8) may be manifested as a mesenteric mass, stricture, spiculation, ulceration, or tethering of small bowel loops. If multiple adjacent recesses are affected, palisading of small bowel loops, in which narrowed loops are aligned in parallel configuration, may be seen on barium studies.^{5,6,15,63}

SIGMOID MESOCOLON

Infected and malignant fluid from the left inframesocolic space collects on the superior aspect of the sigmoid mesocolon (Fig. 109-9). This may cause a serosal mass effect on the superior aspect of the sigmoid colon on barium enema studies.^{5,6}

Retroperitoneal Spread

The retroperitoneum extends from the pelvic brim inferiorly to the diaphragm superiorly. It is bounded ventrally by the posterior parietal peritoneum and dorsally by the transversalis fascia. The anterior (Gerota) and posterior (Zuckerkandl) limbs of renal fascia divide the retroperitoneum into three major

Figure 109-3 Intraperitoneal spread of tumor: spectrum of imaging findings. **A.** Gross peritoneal tumor implants are present in a patient with ovarian carcinomatosis. **B.** Fluid in the right inframesocolic space (1) cascades down the leaves of the small bowel mesentery, pools at the medial aspect of the cecum, and then overflows into the pelvis (2). Fluid in the left inframesocolic space (3) seeks the pelvis directly or is deposited on the superior aspect of the sigmoid mesocolon and then flows into the pelvis (4). Fluid in the pelvis may ascend the left paracolic gutter (5) but is stopped by the phrenicocolic ligament (PCL). Fluid in the right paracolic gutter (6) ascends to Morison's pouch (7) and then to the subphrenic space (8), where it is stopped by the bare area (BA) of the liver (L). There is potential communication with the lesser sac (LS) through the foramen of Winslow (9). compartments: the anterior pararenal space, the perirenal space, and the posterior pararenal space (Fig. 109-10).⁶⁴⁻⁶⁶

ANTERIOR PARARENAL SPACE

The anterior pararenal space contains the retroperitoneal portions of the alimentary tract: the pancreas; the ascending and descending colon; and the second, third, and fourth portions of the duodenum. Consequently, it is the site of a large number of infectious, neoplastic, and inflammatory disorders, including appendicitis, diverticulitis, pancreatitis, and carcinoma. Fluid collections and gas in the anterior pararenal space tend to

remain on the right or left side, but they may involve both sides if they originate from the pancreas because that organ straddles the space across the midline. Concurrent disease in both anterior pararenal spaces most commonly occurs in patients with pancreatitis.^{64,65,67,68}

The anterior pararenal space is anatomically continuous with the bare area of the liver (Fig. 109-11), the root of the small bowel mesentery, and the transverse mesocolon, and it provides a pathway for widespread dissemination of gastrointestinal disease. Fluid in the anterior pararenal space can flow inferiorly around the caudal border of the renal fascia and then extend posteriorly to involve the posterior pararenal space. At this level,

the lateroconal fascia may disappear as a distinct boundary, permitting direct communication with the properitoneal fat stripe. The inflammatory process may track to the lateral abdominal wall, which accounts for Grey Turner's sign of pancreatitis.^{64,69}

PERIRENAL SPACE

The perirenal space lies within the anterior (Gerota) and posterior (Zuckerkandl) renal fasciae and contains the kidney, adrenal gland, and fat. The left kidney is intimately related to the distal transverse and proximal descending colon.^{70,71}

Figure 109-9 Drop metastases: carcinoma of the stomach metastatic to the sigmoid mesocolon. A barium enema study shows narrowing and spiculation of the mucosa of the sigmoid colon.

The lienorenal ligament, phrenicocolic ligament, transverse mesocolon, and peritoneal reflections of the descending colon merge near the anterior aspect of the left kidney. The right kidney lies adjacent to the descending duodenum and hepatic flexure of the colon. The root of the transverse mesocolon and peritoneal reflections of the ascending colon also lie in this area. Advanced renal infections and neoplasms may break through fascial boundaries and invade the adjacent bowel. Similarly, large neoplasms of the colon may invade the kidneys.^{70,71}

There is evidence of potential communication across the midline between the two perirenal spaces anterior to the lower aorta and inferior vena cava at the level of L3 to L5. This accounts for certain patterns of distribution of hemorrhage after abdominal aortic aneurysm rupture. When the disease process originates in the kidney, however, contralateral extension of fluid is impeded by fibrous septa and by the narrowness of the potentially communicating channel.⁷²

POSTERIOR PARARENAL SPACE

The posterior pararenal space contains primarily fat. Accordingly, it is usually involved secondarily by disease processes rather than being a primary site of disease. Perforations of the sigmoid colon and rectum may gain access to the posterior pararenal space.⁷³ In pancreatitis, fluid may extend directly into this space from the anterior pararenal space inferiorly.⁶⁴ However, most fluid collections seen posterior to the kidney in pancreatitis are caused by separation of the two laminae of the posterior limb of renal fascia.

Collections in the posterior pararenal space usually result from spontaneous retroperitoneal hemorrhage or from disease in contiguous musculoskeletal structures. The posterior pararenal space continues anteriorly as the properitoneal fat line, and disease in this space may obliterate the line.^{64,65}

Figure 109-10 Retroperitoneal anatomy. Axial diagram of the abdomen at the level of the kidneys demonstrates the anatomy of the retroperitoneum. The anterior pararenal space contains the retroperitoneal portions of the alimentary tract: ascending colon, descending colon, duodenum, and pancreas. The perirenal space contains the kidneys and lies between the Gerota fascia and the fascia of Zuckerkandl. The posterior pararenal space contains fat. (Modified from Meyers MA: Acute extraperitoneal infection. *Semin Roentgenol* 8:445-464, 1973.)

Figure 109-11 Hepatic bare area and anterior pararenal space: spread of hemorrhage. Communication between the bare area of the liver and the anterior pararenal space is illustrated in this patient who developed a spontaneous right renal bleed while being treated with anticoagulant drugs. **A.** Hemorrhage from a fractured right kidney is present in the bare area of the liver (yellow arrow). Blue arrow, Pleural effusion. **B.** The renal fracture is identified (arrow), and there is blood in the perinephric space and anterior pararenal space. Note the slitlike inferior vena cava. **C.** The anterior pararenal space is continuous with the bare area of the liver, explaining the findings in **B.** This sagittal drawing depicting the right retroperitoneal spaces also shows the perirenal space, containing the right kidney and adrenal gland, and the posterior pararenal space, which communicates with the inferior aspect of the anterior pararenal space. **D.** The diagram shows the posterior view of the bare area of the liver. LCL, Left coronary ligament; FL, falciform ligament; hv, hepatic veins; RCL, right coronary ligament. (**C** from Meyers MA: *Acute extraperitoneal infection*. *Semin Roentgenol* 8:445–464, 1973. **D** from Arenas AP, Sanchez LV, Albillos JM, et al: *Direct dissemination of pathologic abdominal processes through perihepatic ligaments: Identification with CT*. *RadioGraphics* 14:515–537, 1994.)

Subperitoneal Spread

The subperitoneal space is a large, unifying, anatomically continuous potential space that connects the peritoneal cavity with the retroperitoneum (Fig. 109-12). This space is formed by the subserosal areolar tissue that lines the inner surfaces of the peritoneum and the musculature of the abdomen and pelvis. It contains the branches of the vascular, lymphatic, and nervous systems that supply the viscera. The subperitoneal

space extends into the peritoneal cavity and is invested between the layers of the mesenteries and ligaments that support and interconnect the abdominal and pelvic organs. As such, it provides one large continuous space in which infectious, neoplastic, inflammatory, and hemorrhagic disease may spread in many directions.*

*References 2-4, 6, 7, 65-68, 74, 75.

Figure 109-12 Subperitoneal spaces. Frontal diagram of the posterior parietal wall of the upper abdomen shows the planes of peritoneal reflections that constitute the major ligaments and mesenteries of the subperitoneal space. Anatomic continuity between intraperitoneal structures and between extraperitoneal and intraperitoneal sites is established along the bare areas at the roots of origin of the supporting ligaments and mesenteries. (From Meyers MA, Oliphant M, Berne AS, et al: *The peritoneal ligaments and mesenteries: Pathways of intraabdominal spread of disease*. Radiology 163:593–604, 1987.)

TRANSVERSE MESOCOLON

The transverse mesocolon is the linchpin that unites the various subperitoneal spaces and is a major conduit for focal and distant spread of disease. On the right, the transverse mesocolon is continuous with the duodenocolic ligament; on the left, it is continuous with the phrenicocolic ligament; and centrally, it communicates with the small bowel mesentery (Fig. 109-13).^{2-4,7}

The dissemination of fluid and enzymes in pancreatitis typifies the role of this space in disease spread. The inflammatory changes of pancreatitis can spread to the transverse colon and stomach (both intraperitoneal organs) by the gastrosplenic ligament, lesser sac, and gastrocolic ligament; to the left kidney (a retroperitoneal organ) by the splenorenal ligament; to the liver and gallbladder (intraperitoneal organs) by the hepatoduodenal ligament; and to the right lower quadrant by the root of the small bowel mesentery.^{2-4,67,68,75}

Because the transverse mesocolon inserts on the taenia mesocolica, pancreatic processes carried by this ligament preferentially affect the inferior border of the transverse colon.^{74,75} Fixation of the inferior margin and pseudosacculation of the superior (uninvolved) margin of the transverse colon may be seen on barium enema studies in patients with pancreatic disease. Colon neoplasms and diverticulitis can invade the transverse mesocolon and subsequently spread to the pancreas.²⁻⁴

GASTROCOLIC LIGAMENT AND GREATER OMENTUM

The gastrocolic ligament connects the greater curvature of the stomach to the transverse colon (Fig. 109-14). It is formed by

fusion of the four layers of peritoneum that invest the stomach. These layers descend a variable distance to form the greater omentum and then fuse at the level of the colon.

The potential space between the middle layers of the greater omentum forms the inferior recess of the lesser sac. In most adults, partial fusion of the middle layers prevents the lesser sac from extending below the transverse colon. The greater omentum consists of a trabecular framework of vessels with various amounts of adipose tissue, lymphatics, or macrophages. It has been called the abdominal policeman and is frequently involved by infectious and neoplastic processes.⁷⁶⁻⁷⁹

On the left, the gastrocolic ligament is continuous with the gastrosplenic ligament. On the right, it ends at the gastroduodenal junction, near the hepatoduodenal ligament. Carcinoma of the transverse colon can invade to the greater curvature of the stomach, and gastric neoplasms can spread to the superior aspect of the transverse colon by the gastrocolic ligament.^{74,75,79}

GASTROHEPATIC LIGAMENT

The gastrohepatic ligament is part of the lesser omentum. It joins the gastroesophageal junction and lesser curvature of the stomach to the liver at the fissure of the ligamentum venosum superiorly and the porta hepatis inferiorly. Beneath the diaphragm, the esophagus is invested by the gastrohepatic ligament on the right and the gastrophrenic ligament on the left. The gastrohepatic ligament contains the left gastric artery, coronary vein, and left gastric lymph node chain. The subperitoneal fat of the gastrohepatic ligament continues into the liver as Glisson's capsule. Lymph nodes and blood vessels seen in the gastrohepatic ligament by CT should be smaller than 8 mm in

Figure 109-13 Transverse mesocolon: anatomic relationships and planes of disease spread. **A.** Frontal diagram shows the relationships of the transverse mesocolon (TM). The transverse mesocolon is continuous with the root of the small bowel mesentery (SBM), the splenorenal ligament (SRL), and the phrenicocolic ligament (PCL). **B.** Sagittal diagram through the transverse colon demonstrates preferential spread of pancreatic disease through the transverse mesocolon (TM) inferiorly along the taenia mesocolica–taenia libera (TL) haustra toward the taenia libera–taenia omentalis (TO) row. This constitutes the inferior border of the transverse mesocolon. **C.** Fluid surrounds the middle colic vessels (arrows) of the transverse mesocolon in this patient with pancreatitis. **D.** Sagittal reformatted image shows inflammatory pancreatic fluid traversing the transverse mesocolon to spread (arrow) to the transverse colon. (A from Okino Y, Kiyosue H, Mori H, et al: Root of the small-bowel mesentery: Correlative anatomy and CT features of pathologic conditions. *RadioGraphics* 21:1475–1490, 2001; modified from Meyers MA: *Dynamic Radiology of the Abdomen: Normal and Pathologic Anatomy*, 5th ed. New York, Springer-Verlag, 2000, pp 131–264. B from Meyers MA, Volberg F, Katzen B, et al: *Haustral anatomy and pathology: A new look. II. Roentgen interpretation of pathologic alterations. Radiology* 108:505–512, 1973.)

Figure 109-14 Gastrocolic ligament: normal anatomy and pathology. **A.** Sagittal diagram through the transverse colon demonstrates preferential spread of disease from the stomach, through the gastrocolic ligament, and along the taenia omentalis (TO)–taenia mesocolica (TM) haustral row. This constitutes the superior border of the transverse colon. The taenia libera (TL) is indicated. **B.** Barium enema in a patient with Crohn's disease demonstrates a fistula (arrows) from the transverse colon to the greater curvature aspect of the stomach by way of the gastrocolic ligament. **C.** Direct invasion (arrows) of the superior aspect of the transverse colon along the gastrocolic ligament occurs from a scirrhous carcinoma of the stomach. **D.** Sagittal reformatted image shows gastric cancer invading through the gastrocolic ligament into the superior aspect of the transverse colon (arrow). (A from Meyers MA, Volberg F, Katzen B, et al: *Haustral anatomy and pathology: A new look. II. Roentgen interpretation of pathologic alterations. Radiology* 108:505–512, 1973.)

diameter. Nonenhancing structures larger than 8 mm suggest adenopathy; if they enhance, varices should be considered.⁸⁰

Gastric cancers often spread first to the lymph nodes in the gastrohepatic ligament (Fig. 109-15). The left gastric nodes also receive direct lymphatic drainage from the distal esophagus,

and neoplasms in this region may produce gastrohepatic ligament adenopathy. Because the gastrohepatic ligament is contiguous with the hepatoduodenal ligament, adenopathy may occur in the porta hepatis and the peripancreatic area from spread of a gastric neoplasm. Direct spread of fundal gastric

malignant neoplasms into the left hepatic lobe occurs by means of this ligament and Glisson's capsule.⁴ Infectious, inflammatory, and autoimmune disorders of the liver often cause adenopathy in the gastrohepatic and gastroduodenal ligaments. Lymphoma and carcinoma of the breast, lung, and esophagus may spread to the same ligament.

HEPATODUODENAL LIGAMENT

The hepatoduodenal ligament is formed at the free edge of the gastrohepatic ligament and connects this portion of the peritoneal cavity with the right anterior pararenal space. It extends from the junction of the first and second portions of the duodenum to the porta hepatis and contains the blood vessels and

lymphatics that supply the liver, gallbladder, and biliary tree as well as the common bile duct to its insertion into the ampulla of Vater. Any hepatic or biliary process adjacent to the liver hilum, including the anterior portion of the caudate lobe, can spread by the hepatoduodenal ligament and subsequently extend to the gastrohepatic ligament, gastrocolic ligament, duodenocolic ligament, transverse mesocolon, and falciform ligament. Pancreatic neoplasms invade the porta hepatis by this ligament.⁸¹⁻⁸⁶

DUODENOCOLIC LIGAMENT

The duodenocolic ligament is the right margin of the transverse mesocolon. It provides a pathway for disease spread between the descending duodenum and the junction of the ascending and transverse colon.^{81,87}

GASTROSPLENIC LIGAMENT

The gastrosplenic ligament is formed by the left lateral extension of the peritoneal layers of the greater omentum and connects the greater curvature of the stomach with the splenic hilum. It contains the left gastroepiploic and short gastric vessels. The gastrosplenic ligament provides a pathway for spread of disease between the pancreatic tail, the spleen, and the stomach. Carcinoma of the stomach may spread to the splenic hilum along this ligament. Similarly, carcinoma of the pancreatic tail can spread to the stomach by invading first the splenic hilum and then the stomach by the gastrosplenic ligament. Because the pancreatic tail borders this ligament, this is a fairly common site of pseudocyst formation (Fig. 109-16). Benign gastric ulcers may penetrate into the spleen by this ligament.^{2-4,6,88}

SPLENORENAL LIGAMENT

The splenorenal ligament invests the pancreatic tail and affords communication between the anterior pararenal space, which contains the pancreas, and the perirenal space, which contains the kidney. Although pancreatitis (Fig. 109-17) and carcinoma

Figure 109-15 Spread of gastric cancer into the gastrohepatic ligament. Coronal reformatted CT image shows tumor invasion of the gastrohepatic ligament (black arrow). Peritoneal tumor implants (white arrows) are identified.

Figure 109-16 Gastric cancer spread to the spleen by means of the gastrosplenic ligament.

Coronal (A) and axial (B) images. The subperitoneal space of the gastrosplenic ligament (arrows) is serving as a conduit of tumor spread in this patient with adenocarcinoma of the greater curvature of the stomach.

Figure 109-17 Inflammation of pancreatitis spreading from the pancreas to the left kidney by means of the splenorenal ligament: MRI and CT findings in the same patient. **A.** CT shows fluid inferior to the pancreatic tail that extends into the left perirenal space (arrow). **B.** Fat-suppressed, axial, T2-weighted MR image shows high signal intensity fluid (arrow) lateral to the left kidney in the perirenal space.

of the pancreas can commonly spread through this ligament, renal disease seldom involves the pancreatic tail.^{2-4,6}

PHRENICOCOLIC LIGAMENT

The phrenicocolic ligament is the left lateral extension of the transverse mesocolon. It acts as the suspensory ligament of the spleen, reflects the anatomic splenic flexure of the colon, and is directly continuous with the splenorenal ligament and transverse mesocolon. It can transmit neoplastic and inflammatory disease between the pancreas and the colon, the left kidney, and the spleen.^{2-6,67,68}

SMALL BOWEL MESENTERY

The small bowel mesentery occupies a major portion of the peritoneal cavity as it suspends the small bowel, and it represents an enormous potential space for disease spread.^{2-4,63,67,68} Seeded neoplastic or infectious material associated with free intraperitoneal fluid cascades along the mesenteric leaves in the inframesocolic space and is deposited on the medial aspect of the cecum on the right, on the superior border of the terminal ileum, and on the superior aspect of the sigmoid mesocolon on the left.^{5,6}

The subperitoneal space of the small bowel mesentery is continuous with the bare area of the ascending colon and the transverse mesocolon (Fig. 109-18). The leaves of the small bowel mesentery continue as the posterior peritoneum, overlying the posterior abdominal wall. The connective tissue in the small bowel mesentery merges with the subperitoneal tissue of the retroperitoneum. The subperitoneal tissue continues without interruption inferiorly, from the right lower abdomen over the pelvic musculature and along the lateral pelvic sidewalls. Because this space potentially communicates with the broad ligament, it provides a pathway for bidirectional disease spread between the abdomen and the pelvis.^{2-4,17}

SIGMOID MESOCOLON

The mesocolon or mesentery of the sigmoid colon provides a major avenue for spread of disease between the abdominal cavity and the pelvis. It is directly continuous with the posterior bare area of the colon, the bare area of the rectum, and, in

females, the broad ligament. Diverticulitis usually spreads into and is confined by the sigmoid mesocolon. Carcinoma of the sigmoid colon may spread to the ovary hematogenously or through the mesocolon and then along the broad ligament.^{2-4,7} Similarly, ovarian neoplasms or tubo-ovarian abscesses may directly spread by the broad ligament to the sigmoid mesocolon and subsequently involve the sigmoid colon.^{2-4,7}

BROAD LIGAMENT

The broad ligaments pass from the margins of the uterus to the lateral walls of the pelvis and together with the uterus form a septum across the lesser pelvis, dividing it into two parts. The anterior part contains the bladder and uterocystic recess; the posterior part includes the rectum, cul-de-sac, terminal ileum, and part of the sigmoid colon. These ligaments enclose the subperitoneal space, which includes the uterus, ovaries, fallopian tubes, arteries, nerves, lymphatics, and distal ureters as they enter the bladder. On the right side, communication with the base of the cecum and right inferolateral termination of the small bowel mesentery provides subperitoneal continuity for bidirectional spread of disease between the female pelvic organs and the retroperitoneal and peritoneal organs of the abdomen. On the left, the broad ligament communicates with the sigmoid mesocolon. Tumors of the cecum, appendicitis, Crohn's disease abscesses, and drop metastases can spread to the right ovary by this pathway. Similarly, an ovarian neoplasm or tubo-ovarian abscess may spread to the cecum and terminal ileum.⁷

FALCIFORM LIGAMENT AND LIGAMENTUM TERES

The ligamentum teres is located in the free edge of the falciform ligament and anchors the liver anterosuperiorly to the abdominal wall. Infections and malignant neoplasms in the porta hepatis can penetrate the falciform ligament when they extend along the fissure of the ligamentum teres. The superficial lymphatics of the liver also traverse the falciform ligament, providing additional pathways of disease spread. The ligamentum teres, gastrohepatic ligament, and hepatoduodenal ligament are continuous, deep to the porta hepatis near the left portal vein.^{2-4,89}

CORONARY LIGAMENT AND BARE AREA

The right coronary ligament suspends the right lobe of the liver from behind and together with the left coronary ligament defines the margins of the bare area of the liver. The bare area of the liver is continuous with the anterior pararenal space.^{4,64,65} The inferior vena cava lies within the bare area of the liver, and fluid in the anterior pararenal space can extend ventrally to the inferior vena cava (see Fig. 109-11), close to the epiploic foramen.^{2-4,89}

Extraperitoneal Spread

ILIOPSOAS MUSCLE ROUTE

Intraperitoneal and retroperitoneal disease can penetrate fascial boundaries and spread into the extraperitoneal space and its major muscles, the psoas and iliacus. These muscles are quite long and provide a pathway for disease spread from the level of

the pancreas to the level of the thigh and lesser trochanter. Carcinoma of the colon, pancreatitis, appendicitis, Crohn's disease with fistula formation, diverticulitis, ischiorectal abscess, periureteral abscess, renal abscess, traumatic perforation of the rectum, and foreign body perforation of the gut can potentially involve the psoas muscle and extend into the extraperitoneal space.⁹⁰⁻⁹⁴

SACROSCIATIC NOTCH ROUTE

Pelvic neoplasms arising from the rectosigmoid, prostate, uterus, and cervix can involve the extraperitoneal pelvic compartment and gluteal regions by intrinsic involvement of the piriformis and the obturator internus muscles or their surrounding fascial planes. Direct compression of the sciatic or sacral nerve may cause pain, simulating a cauda equina lesion. Similarly, hematoma or abscess fluid may spread from the pelvis to the gluteal region and vice versa.^{90,92}

The piriformis muscle can spread disease through the greater sciatic foramen onto the greater trochanter. The obturator internus muscle can be a disease conduit as it courses through the lesser sciatic foramen to insert on the greater trochanter.^{91,95}

OBTURATOR FORAMEN ROUTE

Infections and hernias may spread through the obturator foramen into the groin and legs and onto the lesser trochanter.

ABDOMINAL WALL ROUTE

The spread of infection in the abdominal wall is facilitated by copious fat and long muscle groups that contain few impeding fasciae. Abdominal wall disease may result from direct spread

of disease (e.g., Crohn's disease, perforated neoplasm) or from indirect spread from the peritoneal cavity by the falciform ligament. Contiguous spread of tumor to the abdominal wall is most frequently seen in tumors that arise in superficial organs, such as the omentum, transverse colon, gallbladder, and bladder.⁹⁶⁻⁹⁸

Conclusions

The abdominal and pelvic organs and their supporting ligaments, peritoneal reflections, and mesenteries form a complex interconnecting network. This unifying concept explains the presence of abdominal disease at sites distant from its origin. Knowledge of the various pathways of spread provides a clearer understanding of many disease processes and can help tailor the imaging approach to abdominal and pelvic disease.

Transjugular Intrahepatic Portosystemic Shunt

Surgical Shunting

Ascites is the pathologic accumulation of fluid in the peritoneal cavity. It is a common clinical finding that can be associated with a large number of diseases. In some disorders, peritoneal fluid represents a complication or late manifestation of disease, whereas in others, it is the first clinical expression of the disease process. For this reason, early detection and characterization of ascites and other peritoneal fluid collections are important.

Pathophysiology

The causes of ascites are protean and are listed in [Box 110-1](#). The imaging features that can help differentiate the various causes are listed in [Table 110-1](#). Although ascites may merely reflect generalized third-space fluid loss in conditions such as congestive heart failure, chronic renal disease, and massive fluid overload, it is more commonly related to intra-abdominal factors that produce peritoneal fluid more rapidly than it can be absorbed.¹⁻⁴ Cirrhosis and neoplasm are the two most common causes of ascites in the Western world. Tuberculosis and cirrhosis are the predominant causes worldwide.^{4,5}

Clinical Findings

A small amount of ascites is often asymptomatic, but as the amount of fluid increases, the patient develops a sense of fullness, discomfort, and abdominal distention. With tense ascites, the patient may experience respiratory distress, nausea, vomiting, anorexia, fever, or pain. Weight gain usually accompanies the fluid accumulation, unless it is associated with alcoholism, neoplasm, or poor nutrition, in which case the patient's weight may remain stable or drop.⁴

The physical diagnosis of ascites is difficult, unless there is at least 1.5 to 2 L of fluid in the peritoneal cavity.⁶ Physical examination reveals abdominal distention, with bulging flanks that are dull to percussion or a fluid wave. As little as 300 to 400 mL of fluid can be demonstrated by placing the patient on hands and knees and producing a dull sound by percussion over the dependent abdomen (i.e., the puddle sign).⁷ Umbilical hernias, penile or scrotal edema, and pleural effusion are indirect signs of ascites. Flank dullness is the most sensitive sign, and a fluid wave is the most specific sign of ascites on physical examination.²

Diagnostic Paracentesis

Diagnostic paracentesis is indicated for any patient who develops ascites for the first time and for patients with chronic ascites who develop fever, encephalopathy, or abdominal pain.⁸ Paracentesis for small volumes should be performed under sonographic guidance with an 18- or 20-gauge, plastic-sheathed catheter to avoid injury to the liver, spleen, or gut. With massive ascites, a blind tap can be performed 2 to 3 cm beneath the umbilicus in the midline to reduce the chance of bleeding along the linea alba or at a left-sided McBurney point to avoid injuring an enlarged liver or spleen.^{2,4} Fluid should be analyzed for protein, lactate dehydrogenase, amylase, blood cell count with differential, bacteriologic and cytologic tests, pH, and triglycerides.^{2,4,8}

Types of Peritoneal Fluid Collections

TRANSUDATES

Transudates are clear and colorless fluid collections with a protein content less than 2.5 g/dL and specific gravity less than 1.016. They are most commonly seen in patients with cirrhosis, long-standing heart failure, constrictive pericarditis, chronic

BOX 110-1 CAUSES OF ASCITES

PORTAL HYPERTENSION RELATED

- Cirrhosis
- Alcoholic hepatitis
- Fulminant hepatic failure
- Heart failure
- Constrictive pericardial disease
- Budd-Chiari syndrome
- Hepatic veno-occlusive disease
- Liver metastases

PERITONEAL DISEASES

- Carcinomatosis from ovarian, colon, gastric, pancreatic, hepatic, and other neoplasms
- Mesothelioma
- Tuberculosis
- Fungal infections
- Pyogenic infections
- Peritonitis
- Sarcoidosis
- Vasculitis
- Eosinophilic gastroenteritis
- Whipple's disease

MISCELLANEOUS CAUSES

- Myxedema
- Pancreatic ascites
- Chylous ascites
- Hemoperitoneum due to trauma or tumor hemorrhage
- Ruptured ovarian cyst
- Nephrotic syndrome
- Malnutrition
- Protein-losing enteropathy
- Hypoalbuminemia
- Meigs' syndrome
- Ovarian hyperstimulation syndrome

renal failure, hypoproteinemia, anasarca, and Budd-Chiari syndrome.^{2,4,8-10}

EXUDATES

Exudates are fluid collections with a density greater than 1.016 and a protein content greater than 2.5 g/dL. They are often yellowish but may be hemorrhagic in patients with metastatic peritoneal infiltration, infection, tuberculosis, or pancreatitis. An ascitic fluid-to-serum lactate dehydrogenase ratio greater than 0.6 suggests malignant disease. A polymorphonuclear leukocyte count greater than 500/mm³ suggests infection or pancreatic ascites, and a mononuclear cell count larger than 500/mm³ is commonly seen with tuberculosis.¹¹ A pH less than 7.35 also indicates tumor, infection, or pancreatitis. A fluid amylase value greater than 1000 U/L and a protein value greater than 3 g/dL are usually associated with pancreatic ascites.¹²

HEMORRHAGIC ASCITES

Hemorrhagic ascites usually occurs in the setting of hepatic or splenic trauma resulting from an accident (Fig. 110-1A), surgery, or biopsy. Sanguineous ascites is usually caused by malignant disease but may occur in patients with tuberculosis or chronic pancreatitis.

PUS

Pus is often present in the peritoneal cavity in patients with acute peritonitis. It is most often seen in young patients with pneumococcal or hemolytic streptococcal peritonitis. When peritonitis is caused by a perforated viscus (Fig. 110-1B), appendicitis, diverticulitis, or tubo-ovarian abscess, signs and symptoms are typically impressive, but the amount of intraperitoneal fluid is relatively small. The presence of more than 500 leukocytes/mm³ is indicative of infected ascites.^{9,13}

CHYLOUS ASCITES

Chylous ascites is a collection of yellowish white, milky fluid that results from obstruction or disruption of lymph flow

TABLE 110-1 Imaging Features of Benign and Complicated Ascites

Imaging Modality	Features Suggesting Benign Transudate	Features Suggesting Complicated Ascites
Ultrasonography	Anechoic collection Compressible collection Follows contours of gut and solid organs Bowel loops freely float in fluid to center of abdomen	Internal echoes (may represent blood, crystals, infection, tumor) Fluid does not conform to available spaces but displaces gut and solid organs Loculation (may represent tumor, infection, adhesion, inflammation)
Computed tomography	Seen first in cul-de-sac and Morison's pouch Uniform low attenuation (0-20 HU) Bowel loops freely float in fluid to center of abdomen	Loculation (may represent tumor, infection, adhesion, inflammation) High fluid attenuation (>30 HU suggests blood but may have hemoperitoneum with fairly normal attenuation) Delayed contrast enhancement (may indicate tumor or infection)
Magnetic resonance imaging	Low signal intensity on T1-weighted image Very high signal intensity on T2-weighted image Bowel loops freely float in fluid to center of abdomen	T1 relaxation shorter with exudates due to protein, tumor, or blood Acute blood (<48 hr) has low signal intensity on T1- and T2-weighted images due to deoxyhemoglobin Intermediate-age blood (2-7 days) has high signal intensity on T1-weighted image and low signal intensity on T2-weighted image due to methemoglobin Delayed contrast enhancement (may indicate tumor or infection) Loculation (may represent tumor, infection, adhesion, inflammation)

Figure 110-1 Types of ascites. **A.** Laparoscopy demonstrating a post-traumatic hemoperitoneum. **B.** Pus in the peritoneal cavity resulting from a perforated viscus. **C.** Pseudomyxoma peritonei.

through the cisterna chyli and thoracic duct.^{4,9} The milky appearance results from the presence of fat (mainly triglycerides in amounts greater than 400 mg/dL) and small amounts of cholesterol and phospholipid. Triglyceride levels may treble after a fatty meal. The causes of chylous ascites include blunt, penetrating, and surgical trauma; malignant infiltration of the cisterna chyli by lymphoma or carcinoma of the pancreas, stomach, colon, or ovary; left subclavian vein thrombosis; and tuberculous lymphadenitis. Cirrhosis, nephrotic syndrome, protein-losing enteropathy, congenital lymphatic disorders, chronic lymphocytic leukemia, sarcoidosis, and extremely high right-sided heart pressure that alters lymph flow are less common causes of chylous ascites.^{3,14-16} The discovery of milky ascites in an adult mandates a careful search for malignant disease, particularly lymphoma.¹⁷

NEONATAL ASCITES

Neonatal ascites may result from posterior urethral valves, perforated bladder, or urethral atresia that produces urine ascites. Ileal atresia, ileal perforation, ileal volvulus, ischemia, cardiac failure, and infections can also result in neonatal ascites.¹⁸

PSEUDOMYXOMA PERITONEI

Pseudomyxoma peritonei is characterized by the massive accumulation of gelatinous, mucinous material in the peritoneal cavity (Fig. 110-1C), mesentery, and omentum.¹⁹ It is produced by metastatic parietal and visceral peritoneal implants that are seeded after rupture of benign or malignant mucin-secreting tumors of the appendix or ovary. Less commonly, mucinous

tumors of the pancreas, stomach, colon, uterus, bile duct, urachus, omphalomesenteric duct, or pancreas cause pseudomyxoma peritonei.³

BILE ASCITES

Bile ascites can develop after trauma, cholecystectomy, biliary tract surgery, hepatic surgery, liver biopsy, and percutaneous biliary drainage. These collections typically occur in the right or the left supramesocolic spaces.

PANCREATIC ASCITES

Virtually all patients with clinically significant pancreatitis have peripancreatic fluid collections, most of which resolve within 6 weeks (see Chapter 96). These collections most often occur in the lesser sac and anterior pararenal space. Fluid accumulation in the greater peritoneal sac usually occurs in the setting of severe pancreatitis “burning” the peritoneum, in trauma, or after surgical resection.^{20,21} The cause of pancreatic ascites in all cases is disruption of the pancreatic duct. Endoscopic retrograde pancreatography is diagnostic in these cases.^{21,22} Pancreatic ascites should be part of the differential diagnosis of every patient with chronic ascites who has a history of pancreatitis, alcoholism, or abdominal trauma.

URINE ASCITES

Urine ascites usually follows a bladder tear or injury to another portion of the collecting system after direct trauma, seat belt-caused injury, or use of instrumentation. Most urinomas

accumulate in the retroperitoneum rather than in the peritoneal cavity.³

CEREBROSPINAL FLUID ASCITES

Cerebrospinal fluid ascites and pseudocyst formation account for 4.5% of all ventriculoperitoneal shunt complications. This type of ascites occurs when the peritoneal cavity fails to absorb the fluid or when lymphatic disruption diminishes return of fluid to the bloodstream. If the collection elicits an infectious or inflammatory response, adhesions may develop and cause encystation of the cerebrospinal fluid.³

Pathways of Fluid Distribution

A number of factors determine the distribution of fluid in the peritoneal cavity: volume; peritoneal pressures; position of the patient; region of origin; rate of fluid accumulation; presence of adhesions; density of the fluid; and peritoneal, mesenteric, and omental ligaments and reflections.²³⁻³⁵ The pathways of intraperitoneal fluid distribution are summarized in Figure 110-2. Briefly, fluid in the inframesocolic space seeks the pelvis: on the right, through the leaves of the small bowel mesentery, and on the left, through the medial side of the rectosigmoid.

Figure 110-2 Common pathways of intraperitoneal fluid spread. Fluid in the right inframesocolic space (1) cascades down the leaves of the small bowel mesentery, pools at the medial aspect of the cecum, and then overflows into the pelvis (2). Fluid in the left inframesocolic space (3) seeks the pelvis directly or is deposited on the superior aspect of the sigmoid mesocolon and then flows into the pelvis (4). Fluid in the pelvis may ascend the left paracolic gutter (5) but is stopped by the phrenicocolic ligament (PCL). Fluid in the right paracolic gutter (6) ascends to Morison's pouch (7) and then to the subphrenic space (8), where it is stopped at the bare area (BA) of the liver (L). There is potential communication with the lesser sac (LS) through the foramen of Winslow (9). AC, ascending colon; DC, descending colon; R, rectum; S, spleen; SC, sigmoid colon; TC, transverse colon.

After fluid fills the pouch of Douglas, which is the most dependent portion of the peritoneal cavity, it fills the lateral paravesical recesses and then ascends the paracolic gutters. On the left, its cephalad extent is limited by the phrenicocolic ligament. Fluid in the right paracolic gutter, which structure represents the main communication between the upper and lower abdominal compartments, reaches Morison's pouch and subsequently the right subphrenic space.^{34,35} This is discussed more fully in Chapter 108.

Radiologic Findings

CHEST RADIOGRAPHY

Elevation of the diaphragm, with or without sympathetic pleural effusions (i.e., hepatic hydrothorax), is seen in patients with massive ascites. The cause of the ascites can sometimes be suggested by the chest radiograph. With chylous effusions, a superior mediastinal mass with tracheal deviation may be seen; pericardial calcification or effusion and mediastinal adenopathy are also helpful signs.^{3,36,37}

In patients with hiatal hernia, massive ascites can cause a mediastinal pseudotumor as fluid passes through the esophageal hiatus into the posterior mediastinum.^{38,39} This pseudotumor is caused by the fact that the stomach remains covered by peritoneum to the level of the gastroesophageal junction, regardless of where this point lies. Sometimes, the ascites may enlarge the hernial sac out of proportion to the size of the gastric pouch and cause dysphagia and produce a retrocardiac mass visible on barium studies. Cyclic negative intrathoracic pressure created during respiration may provide an alternative route for clearance of peritoneal fluid through defects in the tendinous diaphragm.^{37,40}

PLAIN ABDOMINAL RADIOGRAPHY

Plain radiographs are insensitive for the diagnosis of ascites and have been replaced by cross-sectional imaging. More than 500 mL of fluid is usually required for ascites to be diagnosed on plain radiographs.^{3,41,42}

Indirect signs of ascites on plain radiographs are often nonspecific or helpful only in the presence of massive peritoneal fluid: diffuse abdominal haziness, bulging of the flanks, indistinct psoas margins, poor definition of the intra-abdominal organs, erect-position density increase, separation of small bowel loops, and centralization of floating gas containing small bowel.^{3,4,42} The direct signs of ascites are more reliable and specific. In 80% of patients with ascites, the lateral liver edge is medially displaced from the adjacent thoracoabdominal wall (i.e., the Hellmer sign). Obliteration of the hepatic angle (visible in 80% of normal patients) is a close corollary to the Hellmer sign and is related to the fact that fluid in the superior mesocolic space accumulates around the margins of the liver (e.g., Morison's pouch).^{3,41-44} In the pelvis, fluid accumulates in the rectovesical pouch, then spills into the paravesical fossae. This fluid produces symmetric densities on both sides of the bladder, producing a dog's ear or a Mickey Mouse appearance, which is another good sign of ascites.⁴¹⁻⁴⁴ Another direct sign of ascites is medial displacement of the cecum and ascending colon and lateral displacement of the properitoneal fat line. This sign is present in more than 90% of patients with significant ascites.

Figure 110-3 Ascites: sonographic findings. **A.** The sonogram of transudative ascites (A) in a patient with cirrhosis of the liver shows anechoic fluid and an echogenic liver. **B.** Mural thickening of the gallbladder (arrowhead) is seen in this patient with cirrhosis and ascites (A). Gallbladder wall thickening in the presence of ascites suggests benign disease. Normal mural thickness in the presence of ascites suggests malignant disease. **C.** The sonogram shows malignant ascites in a patient with carcinomatosis due to gastric cancer. Notice the echogenic fluid (A) and bowel loops (arrows) that are tethered posteriorly. Normally, these loops should be freely flowing. **D.** Peritoneal implants (arrows) are present in this patient with carcinomatosis.

BARIUM STUDIES

When the peritoneal fluid is malignant, barium studies may reveal metastatic serosal implants, mechanical small bowel obstruction, or the fixed colon sign, in which no change in colon position or course is observed on pre-evacuation and postevacuation radiographs. Large fluid collections in the lesser sac may simulate a large retrogastric mass on an upper gastrointestinal examination.

ULTRASONOGRAPHY

Real-time sonography is the easiest and most sensitive technique for detection of ascitic fluid.⁴⁵⁻⁴⁹ Volumes as small as 5 to 10 mL can be routinely visualized. Small amounts of fluid are commonly seen in the cul-de-sac of normal women during all phases of the menstrual cycle.⁵⁰

On sonographic examination, uncomplicated ascites appears as a homogeneous, freely mobile, anechoic collection in the

peritoneal cavity that demonstrates deep acoustic enhancement (Fig. 110-3A, B). Free ascites does not displace organs but typically insinuates itself between them, contouring to organ margins and demonstrating acute angles where the fluid borders the organ. The fluid compresses with increased transducer pressure and shifts with a change in the patient's position.⁵¹⁻⁵⁶

Benign ascites can occasionally cause perplexing sonographic artifacts. Perihepatic ascites may cause apparent discontinuity in the diaphragm as a result of reflection of the sound beam at the liver-fluid interface.⁵⁷ Echogenic hepatic pseudotumors can be seen in patients with a nodular liver surface. In this artifact, a focal concavity of the liver surface can act as an acoustic lens and transmit sound in a fashion analogous to the way in which a posterior wall of a cyst does.^{53,58} Other sources of confusion are the appendices epiploica of the colon, which can be mistaken for mesenteric or peritoneal metastatic implants.⁵⁹

The smallest amounts of fluid tend to collect in Morison's pouch and around the liver as a sonolucent band. Fluid may collect anteriorly, as a result of the capillary effect of the narrow

space between bowel loops and viscera.^{34,35,54} In a study of patients with ascites from liver disease, 92% had ascites around the liver, 77% in the pelvis, 69% in the paracolic gutters, and 63% in Morison's pouch.⁵² Although the pouch of Douglas is the most common location for the fluid accumulation of ascites, an overdistended bladder may obscure and displace the fluid to the peritoneal reflection adjacent to the uterine fundus—the so-called triangular fluid cap.^{50,54} In doubtful cases, changes in position produce significant alterations in the location, shape, and size of the fluid. Small amounts of intraperitoneal fluid are readily identified in the cul-de-sac, pouch of Douglas, and Morison's pouch. With more fluid, ascites can be identified in the paracolic gutters.^{45,52,54}

With massive ascites, the small bowel loops have a characteristic polycyclic, "lollipop," or arcuate appearance as they are arrayed on either side of the vertically floating mesentery. The intraluminal gas content and amount of mesenteric fat determine whether the small bowel loops float. In emaciated patients, the entire small bowel mesentery and gut may sink because of the paucity of mesenteric fat.^{45,52,54} The transverse colon and sigmoid colon usually float on top of the fluid because of the nondependent position of their gas content when the patient is supine. The ascending colon and descending colon do not float because they are fixed in the retroperitoneum.^{54,56} In some patients with massive ascites, the right kidney may also be displaced anteriorly and laterally because fluid in the right paracolic gutter exploits the lack of peritoneal attachment between the right renal fascia and liver or diaphragm.⁵⁹

Certain sonographic patterns suggest that the ascites may be an infected, inflammatory, or malignant exudate (Fig. 110-3C, D): coarse internal echoes (i.e., blood), fine internal echoes (i.e., chyle), multiple septa (i.e., tuberculous peritonitis or pseudomyxoma peritonei), loculation or atypical fluid distribution, matting or clumping of bowel loops, and thickening of interfaces between the fluid and adjacent structures.^{54,55,59-63} Absence of these findings does not entirely exclude an exudate because these complicated fluid collections may fulfill the sonographic criteria for transudates in one fourth of cases.^{54,55,60,61}

In malignant ascites, the bowel loops do not float freely but may be tethered along the posterior abdominal wall or plastered to the liver or other organs, or they may be surrounded by loculated fluid collections. Bowel loops are considered matted or infiltrated if they cannot be moved apart with compression by the transducer or if they fail to separate with fluid despite changes in the patient's position.^{51,60}

Loculated ascites usually indicates a malignant process or one associated with adhesions and bowel strictures.^{51,60} Loculated ascites usually has rounded or bulging contours, is not compressible with increased probe pressure, does not conform to the margins of organs, and shows no movement with changes in the patient's position.⁵¹

Another sign of malignant ascites is the presence of concordant fluid collections in the greater and lesser peritoneal sacs.⁶⁴ The significance of this finding is discussed in the section on computed tomography (CT). On sonographic evaluation, these fluid collections produce a butterfly- or wing-shaped lucency separated by the lesser omentum or gastrocolic ligament.⁶⁵

The presence or absence of gallbladder wall thickening is another predictor of benign or malignant ascites (see Fig.

110-3B). Most patients (95%) with carcinomatous peritonitis have a gallbladder wall less than 3 mm thick.^{64,66,67} Mural thickening of the gallbladder (>3 mm) is associated with benign ascites in 82% of cases.^{64,66,67} This thickening of the gallbladder is primarily a reflection of cirrhosis and portal hypertension. Benign, transudative ascites frequently accompanies these disorders.⁶⁸

The sonographic appearances of pseudomyxoma peritonei vary: an exudate with numerous echoes; highly echogenic masses containing numerous scattered cystic spaces; large intraperitoneal, septate, cystic-appearing masses; numerous thick-walled, multiseptate, fluid-filled masses; scalloping of the liver edge; and multiple rounded, echodense masses, which may cast a shadow resulting from calcification.^{54,69,70}

The sonographic appearance of bilomas is nonspecific, and needle aspiration is essential to confirm the diagnosis. Bilomas are usually anechoic collections that are located adjacent to hepatic or biliary structures, demonstrate acoustic enhancement, and have sharp margins.^{3,54}

The appearance of cerebrospinal fluid ascites is also nonspecific. A small amount of free intraperitoneal fluid is a normal finding in patients with a ventriculoperitoneal shunt and suggests normal shunt function. Its absence does not indicate malfunction. However, a localized fluid collection in association with the tip of the shunt tube is pathologic and implies malfunction.^{3,54,71}

The sonographic appearance of hemorrhage is highly variable and depends on the frequency of the transducer. Fresh hemorrhage imaged with 2.25- and 3.0-MHz transducers is typically anechoic with increased sound transmission.⁷² At 5.0, 7.5, and 10.0 MHz, the clot is intensely echogenic. This echogenicity is transient and usually disappears within 96 hours, as the clot undergoes hemolysis. As the clot organizes, internal echoes are generated that disperse evenly throughout the fluid or layer dependently. Chronic hematomas often have coarse clumps of highly echogenic material. With time, the clots may become completely anechoic seromas.^{3,54}

Although the sonographic findings of hematomas are nonspecific, in the appropriate clinical setting of trauma, acute anemia, blood loss, or pelvic pain, certain findings can be most instructive. For example, the presence of highly echogenic material in the cul-de-sac may be helpful in diagnosis of pelvic hemoperitoneum because most other pelvic fluid collections are predominantly anechoic, with low-level echoes.^{59,72}

COMPUTED TOMOGRAPHY

Ascites is well demonstrated by CT. Small amounts of ascitic fluid localize in the right perihepatic space, the posterior subhepatic space (i.e., Morison's pouch), and the pouch of Douglas.⁶⁴ When larger amounts of ascites are present, the fluid accumulates in the paracolic gutters, causing progressive centralization of bowel loops.⁴⁵ The fluid may accumulate in a triangular configuration within the leaves of the small bowel mesentery or adjacent to bowel loops.⁷³ A massive amount of fluid distends the peritoneal spaces.

It is usually difficult to characterize the nature of a peritoneal fluid collection on the basis of CT density,⁷⁴ but several general rules are helpful.⁷⁵ Simple ascites appears as a low-density collection of fluid (Fig. 110-4A) with an attenuation value ranging from 0 to 30 Hounsfield units (HU). The density of the ascitic fluid increases with increasing protein content

Figure 110-4 Ascites: CT features. **A.** Benign, transudative ascites (A) in a patient with cirrhosis and portal hypertension. A recanalized umbilical vein (*straight arrow*) and varices in the gastrohepatic ligament (*curved arrow*) can be seen. **B.** Hemoperitoneum and the sentinel clot sign are demonstrated in a patient with splenic trauma and active extravasation of contrast material (*arrow*). Note the higher density peritoneal fluid adjacent to the spleen (64 HU) and lower density fluid (36 HU) adjacent to the liver. **C.** Complicated ascites from an infection or tumor can cause retraction and a stellate appearance (*arrows*) of the mesentery. This patient had carcinomatosis from colon cancer. **D.** CT of a patient with ovarian cancer shows fluid associated with an omental cake (*arrows*), indicating carcinomatosis. The omental cake is caused by complete replacement of the omental fat by tumor. **E.** Coronal multiplanar reconstruction image shows omental cake (*straight arrows*), liver metastases (*arrowhead*), and ascites (*curved arrow*) in a patient with metastatic colon cancer. **F.** Fluid is identified in the lesser sac (*star*) and the greater peritoneal cavity. This finding and the abnormal enhancement and thickening of the peritoneum (*arrow*) suggest carcinomatosis in this patient with ovarian cancer.

and with exudates.^{3,32} Similarly, acute intraperitoneal hemorrhage can often be distinguished from other fluid collections because it has an attenuation value greater than 30 HU⁷⁴ (Fig. 110-4B). The CT characteristics of blood within the peritoneal cavity change in a matter of hours or days, in contrast with intracerebral bleeds, in which lysis of blood and consequently CT density evolve during days or weeks. These temporally dramatic changes are related to the impressive fibrinolytic activity of the peritoneum. High-density blood implies that the bleeding is recent or rapid and mandates careful observation of the patient.^{75,76} Several caveats are warranted in interpreting high-attenuation fluid. Delayed enhancement of ascites may follow infusion of a large dose of contrast medium for delayed hepatic CT scanning.^{77,78}

Chylous ascites attributable to traumatic or neoplastic disruption of the cisterna chyli has an attenuation value less than 0 HU.¹⁷ The presence of intraperitoneal and extraperitoneal water-density fluid (i.e., chyle) suggests chylous ascites in a trauma patient because most water-density abdominal fluid collections are confined to one peritoneal compartment.^{76,79,80} However, it is usually difficult to characterize the underlying cause of ascites on the basis of CT density.^{74,75}

After the CT diagnosis of ascites has been established, it is important to determine the cause. A number of CT features suggest neoplasia. Hepatic, adrenal, splenic, or lymph node lesions associated with masses arising from the ovary, gut, or pancreas are suggestive of malignant ascites.⁸⁰ However, these tumors are often advanced and clinically evident before the onset of ascites. Peritoneal seeding from ovarian, gastric, pancreatic, or colon metastases may produce nodular soft tissue masses along the peritoneal surface or along the liver capsule.^{81,82} Sometimes, the peritoneum shows thickening or abnormal enhancement, but these later findings are nonspecific (Fig. 110-4C, D). Omental and mesenteric masses are also commonly seen in carcinomatosis (Fig. 110-4E, F).

Patients with malignant ascites tend to have proportional fluid collections in the greater and lesser sacs, whereas in patients with benign transudates, the fluid is seen primarily in the greater sac and not in the lesser omental bursae.^{62,64} Similarly, benign fluid collections resulting from disease in structures that border the lesser sac (e.g., pancreatitis, posterior penetrating gastric ulcer) tend to remain confined to the lesser sac.⁸³ The foramen of Winslow is more a potential than a widely patent avenue of communication between these peritoneal bursae.^{62,83,84}

In malignant ascites, the small bowel may be tethered along the posterior abdominal wall (see Fig. 110-5C) or have a stellate appearance. Normally, gas-filled or contrast-filled gut should be able to reach the anterior abdominal wall and float freely and centrally in benign ascitic fluid.^{67,85-87} As observed sonographically, gallbladder wall thickening is another useful sign of benign ascites.

On CT scans, pseudomyxoma peritonei may be manifested as scalloping of the liver edge, as large low-attenuation fluid collections that appear to have multiple cysts, or as low-density masses with calcification. A sterile, nonhemorrhagic biloma has a nonspecific appearance and an attenuation value less than 20 HU. These bilious collections cannot be specifically distinguished from cysts, pseudocysts, loculated ascites, or abscess. Urine ascites also has a nonspecific CT appearance on unenhanced scans. Intravenously administered contrast medium often accumulates in these collections. Cerebrospinal

fluid ascites also has a nonspecific appearance, and infection usually cannot be excluded on the basis of CT appearance alone.³³

MAGNETIC RESONANCE IMAGING

Transudates have long T1 and T2 relaxation times (Fig. 110-5A, B). Exudates demonstrate intermediate to short T1 values and long T2 values. The T1 relaxation time of fluid decreases with increasing protein content.⁸⁸⁻⁹⁰ Although magnetic resonance imaging (MRI) offers potential for differentiating various types of abdominal fluid collections, it is not sufficiently specific to obviate paracentesis.³²

MRI is another method for detecting peritoneal fluid and in several studies was shown to be superior to CT in detecting peritoneal tumors and carcinomatosis (Fig. 110-5C, D). MRI sequences used included T1-weighted, fast spin-echo T2-weighted, immediate and delayed gadolinium-enhanced, breath-hold, and fast multiplanar sequences with fat saturation. A 2% barium solution is given orally to provide an effective source of stabilized water and bowel distention that facilitates depiction of serosal and adjacent peritoneal tumors.⁹¹⁻⁹³

Differentiation of Ascites

DIFFERENTIATION OF ASCITES FROM PLEURAL FLUID

In patients with small pleural effusions or ascites, it may be difficult to determine whether the fluid is supradiaphragmatic or subdiaphragmatic. Four useful signs have been described on CT and ultrasound studies.^{40,94-100}

Bare Area Sign

The right lobe of the liver is directly attached to the posterior abdominal wall and diaphragm by the coronary ligament, without intervening peritoneum. Intraperitoneal fluid cannot accumulate posterior to the liver (Fig. 110-6). If fluid is identified dorsal to the liver and medial to the attachment of the right superior coronary ligament, it must lie in the posterior sulcus of the pleural space. The spleen also demonstrates a bare area that maintains a constant relation to the superior ventral aspect of the left kidney, specifically Gerota's fascia. This bare area is about 2 cm long and is usually seen on two adjacent CT sections. It is postulated that the point of reflection of the splenorenal ligament at the bare area is correlated anatomically with the intermediate ridge of the spleen.¹⁰⁰

Diaphragm Sign

Fluid "inside" the diaphragm is ascites, whereas fluid "outside" the diaphragm is pleural effusion.⁹⁹

Displaced Crus Sign

The diaphragmatic crura represent focal muscle thickenings near the midline. If the crus is displaced away from the spine by an abnormal fluid collection, the fluid is pleural in origin. Ascites lies lateral and anterior to the crus.⁹⁷

Interface Sign

The location of a fluid collection can also be suggested by its interface with the liver. The apparent interface between ascites

Figure 110-5 Ascites: MR features. Coronal T1-weighted (A) and T2-weighted (B) scans of the upper abdomen show benign fluid in Morison's pouch (MP), left paracolic gutter (LG), and left subphrenic space (LSS). C. Image of a patient with fibrolamellar hepatoma of the left lobe shows ascites and enhancing Glisson's capsule implants (arrows), indicating peritoneal spread of disease. D. Coronal T2-weighted image shows pseudomyxoma peritonei displacing the gut superiorly. (D courtesy Dr. Rodney H. Reznek, London, England.)

and the liver is sharp and well defined. The interface between pleural fluid and the liver is ill defined. This unsharpness in part reflects volume averaging at curved surfaces (e.g., the diaphragm) and is influenced by slice thickness.⁹⁸

DIFFERENTIATION OF ASCITES FROM SUBCAPSULAR FLUID

Subcapsular hepatic and splenic collections typically conform to the shape of the organ capsule. Subcapsular hepatic collections are confined by the falciform ligament and may extend medially to the attachment of the superior coronary ligament. Medial extension of intraperitoneal fluid collections is stopped by the coronary ligament. On real-time ultrasound studies, subcapsular collections move with the involved organ during respiration, whereas the organs "glide" within intraperitoneal fluid.⁵⁵

Treatment

The rationale for treatment of cirrhotic ascites is to reduce the risk for development of complications, such as spontaneous bacterial peritonitis, and to improve the patient's overall appearance, energy expenditure, and sense of well-being.^{4,101} Respiratory compromise resulting from compression of the diaphragm, anorexia caused by gastric distention, and abdominal discomfort from distention can be improved with therapy.^{3,4} Because these complications occur almost exclusively in patients with moderate to marked ascites, patients with small amounts of fluid usually require no specific treatment. Depending on the method and aggressiveness of therapy, the treatment of ascites is associated with several potentially serious side effects: acid-base and electrolyte abnormalities, hepatic encephalopathy, renal insufficiency, hypovolemia, and a variety of complications associated with the LeVeen peritoneovenous shunt.⁴

Figure 110-6 Differentiating ascites from pleural fluid. **A.** The bare area (BA) sign is demonstrated on this transverse sonogram, which shows pleural fluid posterior to the bare area of the liver. Ascites would not be present in this area because it is excluded from the peritoneum. *RLL*, Right lower lobe of lung. **B.** Diaphragm sign. An axial MR scan shows high signal intensity pleural fluid (arrow) outside the diaphragm (D) posterior to the bare area (BA) of the liver. *A*, Intraperitoneal fluid. **C.** Displaced crus sign. An axial MR image shows a sliver of high signal intensity fluid (arrow) separating the spine from the left hemidiaphragm. **D.** Interface sign. The interface between pleural fluid and liver (arrow) is less distinct than that between ascites and liver.

DIURETICS

Sodium restriction (20 to 30 mEq/day), water restriction (in the presence of hyponatremia), diuretics, and spironolactone constitute the standard medical management for ascites and are effective in 95% of patients.⁴ Therapeutic paracentesis should be reserved for patients who need rapid symptomatic relief of tense ascites.^{101,102}

THERAPEUTIC PARACENTESIS

Early reports stressed the dangers of large-volume paracentesis: hepatic encephalopathy, renal insufficiency, decreased cardiac output, hypovolemia, and hyponatremia. Later studies suggested that large-volume paracentesis of up to 5 L is tolerated well by most cirrhosis patients.¹⁰²⁻¹⁰⁶

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

The transjugular intrahepatic portosystemic shunt (TIPS) procedure has become increasingly popular in the short-term and long-term treatment of patients with refractory ascites (Fig. 110-7).¹⁰⁷⁻¹¹⁰ This procedure is described in Chapter 82.

Figure 110-7 Ascites: therapy. Transjugular intrahepatic portosystemic shunt (TIPS) has become the first-line treatment for refractory massive ascites that fails medical management.

SURGICAL SHUNTING

The peritoneovenous shunt is the best surgical alternative for the less than 5% of patients with medically intractable ascites. First introduced by LeVeen, the shunt functions as a megalympathic that returns the ascitic fluid to the central venous

system. One end of the shunt lies in the peritoneal cavity; the efferent limb lies in the superior vena cava near the entrance of the right atrium. Later shunts (e.g., Denver, Cordis-Hakim) include a pumping mechanism to increase flow or to clear partially occluded shunts. Beneficial effects of these shunts include increased cardiac output, renal blood flow, glomerular filtration rate, urinary volume, and sodium excretion and decreased plasma renin activity and plasma aldosterone concentration.^{111,112}

Despite these apparent benefits, there is no indication that the peritoneovenous shunt improves survival of patients. These shunts are associated with a complication rate of 74% and a mortality rate of 24%.¹¹³ Sepsis, shunt malfunction, and disseminated intravascular coagulation are the major complications. This procedure should be reserved for patients who are truly refractory to medical management and the TIPS procedure.¹¹⁴

Whipple's Disease
Amyloidosis
Extramedullary Hematopoiesis
Trauma and Hemorrhage
Mesenteric Edema
Mesenteric Cysts

Omentum

Radiologic Features
Primary Neoplasms
Metastatic Disease and Lymphoma
Inflammatory Diseases
Miscellaneous Conditions

Anatomy

The mesentery is a part of the peritoneal lining that extends from the posterior peritoneum and suspends bowel loops. The mesentery is composed of two thin layers of fibrofatty tissue, which surrounds and contains the vascular and lymphatic structures supplying either the small bowel or colon. The purpose of the peritoneum and mesentery is to provide a smooth and frictionless surface between the solid organs.¹ The mesentery can be further divided according to whether it suspends small intestine or colon. The small bowel mesentery is obliquely placed in the peritoneal cavity and extends from the ligament of Treitz in the left upper quadrant to the terminal

ileum and ileocecal valve in the right lower quadrant. The transverse mesocolon extends from the pancreas and suspends the transverse mesocolon. The root of the transverse mesocolon passes across the second portion of the duodenum and the head, body, and tail of the pancreas. The plane of the transverse mesocolon can be identified by following the middle colic vessels.

The greater omentum is the continuation of the dorsal mesogastrium inferiorly from the greater curvature of the stomach. This extends inferiorly and doubles back anterior to the transverse colon and then continues posteriorly as the transverse mesocolon. The descending and ascending portions of the greater omentum usually fuse to form a four-layer vascular peritoneal fold (Fig. 111-1).

The peritoneal cavity is divided primarily by the transverse mesocolon into the supramesocolic and inframesocolic compartments. The peritoneal folds in the supramesocolic compartment consist of the falciform, coronary, gastrohepatic, hepatoduodenal, greater omentum, gastrosplenic, splenorenal, and phrenicocolic ligaments. The falciform ligament divides the subphrenic space into the right and left subphrenic spaces. The phrenicocolic ligament extends from the splenic flexure to the diaphragm and limits the cranial extent of the left paracolic gutter. The inframesocolic compartment is subdivided by the small bowel mesentery into the right and the larger left portion extending deep into the pelvis. The left inframesocolic space is limited in the lower left pelvis by the sigmoid mesocolon.

All the ligaments of the peritoneal cavity consist of fused peritoneal layers and form the subperitoneal space, which is a continuous potential space that connects the intraperitoneal compartment to the retroperitoneal compartment. The subperitoneal space also extends to the solid viscera. Thus, any disease process that involves the subperitoneal space can spread bidirectionally to involve either the peritoneal compartment or the retroperitoneum and may involve the abdominal organs.

In most patients, there is sufficient macroscopic fat on computed tomography (CT) to identify the small bowel mesentery, transverse mesocolon, and sigmoid mesocolon. Mesenteric fat has Hounsfield unit measurements of fat elsewhere and measures between -100 and -160 HU.²

Primary Neoplasms

Primary tumors arising from the peritoneum are rare and are usually of mesenchymal origin.

DESMOID TUMORS

These tumors are related to benign but locally aggressive fibroblast proliferation or fibromatosis.³ The morbidity associated with these tumors is related to their locally aggressive behavior with involvement of adjacent organs. They are uncommon,

Figure 111-1 Schematic diagram of the anatomy of the greater omentum. L, Liver; St, stomach; C, colon; P, pancreas; D, duodenum; S, small intestine.

occurring in 2 to 4 per million people per year, and do not show the features of neoplasia. The cause is unknown, but there is an association with pregnancy and estrogen administration. They can occur either sporadically or in association with familial adenomatous polyposis. Familial adenomatous polyposis is an inherited syndrome characterized by innumerable polyps predominantly occurring in the colon. Gardner's syndrome is now considered to be a part of familial adenomatous polyposis, and both these conditions have a mutation of the APC gene.

Desmoid tumors can occur in 5% to 25% of patients with familial adenomatous polyposis.⁴ About half of the abdominal desmoids occur intra-abdominally, and the other half are found in the abdominal wall.⁴ Nearly one third of abdominal desmoids cause pain. Abdominal desmoids can involve the abdominal wall, mesentery, or retroperitoneum (Figs. 111-2 and 111-3). Many of these tumors are often associated with prior surgery, such as colectomy, and can recur at the surgical site. Surgery is thought to stimulate desmoid tumor growth.⁵ The most common site for mesenteric desmoids is at the base of the small bowel mesentery. Tumors can vary in size and range from a few centimeters to extremely large lesions. Desmoids are pseudoencapsulated lesions despite their relatively well defined gross appearance. On microscopic examination, they demonstrate infiltrative margins. Progressive growth may lead to bowel, ureteric, or vascular obstruction and occasionally fistulas.⁶ CT is an excellent imaging study to evaluate desmoid tumors and their relation to surrounding structures and in the follow-up of patients who undergo conservative medical therapy. Desmoid tumors are typically poorly enhancing solid lesions. They can usually be distinguished from postoperative fibrosis by the lack of mass effect of the fibrosis. On ultrasound, these appear as well-demarcated solid masses (Fig. 111-4) containing low to mid-level echoes.⁷ On magnetic resonance imaging (MRI), they

Figure 111-2 Desmoid tumor. Desmoid tumor (arrow) in the mesentery with radiating strands in the mesenteric fat.

Figure 111-3 Desmoid tumor. Desmoid tumor (arrows) involving the abdominal wall.

are of low T1 and low T2 signal intensity (Fig. 111-5) with no or poor enhancement.⁸

MALIGNANT PERITONEAL MESOTHELIOMA

Malignant peritoneal mesothelioma (MPM) is a rare but aggressive tumor that arises from the serosa lining the pleura and the peritoneum.⁹ MPMs account for only 10% to 15% of all mesotheliomas.⁹ These may occur either alone or in conjunction

Figure 111-4 Desmoid tumor. Desmoid tumor (arrows) is a hypoechoic mass on ultrasound.

with pleural mesothelioma. Most patients have a history of exposure to asbestos.^{10,11} There is also a long latent period between exposure and appearance of peritoneal mesothelioma, typically 30 years after the exposure to asbestos. There is a slight male predominance, less than that of pleural mesotheliomas. It has been postulated that the patients with MPM have to have a higher cumulative exposure to asbestos than that of the patients with pleural mesothelioma.¹²

Peritoneal mesotheliomas can be classified into diffuse versus localized mesothelioma. The diffuse type is aggressive as opposed to the localized form, which has a better prognosis with surgery.

Peritoneal mesotheliomas can be classified into epithelial, sarcomatoid, and mixed types on the basis of histologic features. There is great variability in the histologic appearance, making the diagnosis difficult. Sarcomatoid histology is associated with a poor prognosis.¹³ Immunohistochemical staining has been proved to be of great benefit in differentiating MPMs from secondary tumors affecting the peritoneum.¹⁴ MPMs

Figure 111-5 Desmoid tumor. Desmoid tumor (arrows) involving the mesenteric fat on axial T1 (A), axial T2 (B), coronal single-shot fast spin-echo (C), and postcontrast fat-saturated (D) sequences.

produce large amounts of hyaluronic acid and stain with colloidal iron. In contrast, MPMs do not stain positive for the presence of mucin. Symptoms are nonspecific and include abdominal distention, pain, and malaise. Fifty-five percent of patients fail to demonstrate evidence of asbestosis on chest radiographs.

CT is the most useful test in the initial evaluation of patients with increasing abdominal girth and pain. The nodules and masses in mesothelioma enhance with intravenous administration of contrast material. These can be manifested as sites of peritoneal thickening, infiltration, or nodularity (Fig. 111-6). A sheetlike pattern of growth with thickened appearance to the mesentery and bowel wall can also be seen. Bowel loops may be fixed from these infiltrative changes. Calcification is rare in MPMs. They can be associated with variable amounts of ascites. Scalloping or mass effect on adjacent organs is typically seen. On MRI, the nodules are of low T1 signal intensity and intermediate to high T2 signal intensity (Fig. 111-7).¹⁵ The peritoneal nodules can also be seen on dynamic or diffusion-weighted imaging.¹⁶ Positron emission tomography (PET) has a limited role in exact anatomic evaluation of MPMs.¹⁷ All the imaging modalities are limited in their detection of peritoneal nodules

less than 0.5 cm. Peritoneal mesothelioma is associated with poor survival; median survival time is 8 to 12 months after diagnosis.

CT is of help in evaluating for a primary tumor elsewhere in the gastrointestinal or genitourinary tracts, breast, and pancreas. The differential diagnosis includes metastatic disease, primary papillary serous carcinoma of the peritoneum, lymphoma, and granulomatous disease. The presence of marked and enlarged lymphadenopathy favors lymphoma or metastatic disease as the most likely diagnosis. Similarly, calcification of the peritoneal thickening makes MPMs less likely.

The mesenteric infiltration results in a characteristic stellate and fixed appearance.

PRIMARY PERITONEAL SEROUS CARCINOMA

Primary peritoneal serous carcinoma is a rare malignant neoplasm that typically occurs in postmenopausal women. This is a primary tumor of the peritoneum, but the cell origin is thought to be the extraovarian mesothelium with müllerian potential.¹⁸

According to the Gynecologic Oncology group, for a diagnosis of primary peritoneal serous carcinoma to be made, the

Figure 111-6 Mesothelioma. **A.** Patient with peritoneal mesothelioma demonstrating an implant (arrow) along the posterior liver. **B.** Infiltration with masses (arrows) along the mesentery. **C.** Axial PET/CT demonstrating FDG-avid masses (arrows) along the small bowel mesentery. **D.** Coronal PET/CT demonstrating diffuse peritoneal (arrows) involvement.

Figure 111-8 Primary peritoneal papillary serous carcinoma. A. Peritoneal involvement along the liver (arrows). B. Pelvic peritoneal involvement with calcifications (arrows).

ovaries should be normal in size or enlarged from a benign process, and the involvement of the extraovarian sites should be greater than ovarian involvement.¹⁹ The prognosis and treatment are similar to those of serous ovarian carcinoma. Calcification can be seen with this tumor and can help differentiate MPM from this tumor (Fig. 111-8). The CT and the pathologic appearance of primary peritoneal serous carcinoma is similar to that of carcinomatosis from serous ovarian cancer. Assessment for primary ovarian masses should be performed to exclude peritoneal carcinomatosis from ovarian cancer. Psammomatous calcifications can be seen in up to 30% of cases.²⁰

WELL-DIFFERENTIATED PAPILLARY MESOTHELIOMA

This is a rare subtype of mesothelioma that is clinically distinct from MPM. These tumors are seen typically in younger women and are not associated with asbestos exposure.²¹ They may be

detected and removed incidentally. These tumors tend to be small (Fig. 111-9). There is very little written about these tumors in the radiologic literature. These tumors can be manifested as calcifications of the peritoneal surface without associated mass but can also be multiple peritoneal nodules.^{22,23} The clinical course tends to be indolent after surgery. However, these tumors should be observed because of the small risk for development into MPMs.²⁴

MULTICYSTIC PERITONEAL MESOTHELIOMA

This is another rare subtype of peritoneal mesothelioma occurring predominantly in young and middle-aged women along the pelvic peritoneal surface. There is no association to asbestos exposure in these patients. A higher incidence of prior abdominal surgery or pelvic inflammatory disease is seen in these patients.²⁵ This tumor is composed of cysts that vary in size and are separated by septations or fibrous tissue.²⁶ It can appear as

Figure 111-9 Papillary mesothelioma. Incidentally diagnosed small papillary mesothelioma (arrow) within the small bowel mesentery.

a multicystic mass, multiple unilocular cysts adjacent to each other, or a unilocular cystic mass.²³ On ultrasound, this tumor appears as a multiloculated lesion containing anechoic cystic spaces separated by echogenic septations. They can surround the ovaries, and the ovaries may appear entrapped within the cystic mass. On CT, this appears as a well-defined, noncalcified multiloculated cystic mass with enhancing internal septations. Fifty percent of these tumors tend to locally recur after surgical resection.²⁷

There is a slight risk for transformation into a malignant mesothelioma, and long-term follow-up should be performed in these patients.²⁸

DESMOPLASTIC SMALL ROUND CELL TUMOR

This is a rare but extremely aggressive tumor that typically occurs in adolescents and young adults and more commonly in men. The most common clinical complaint is abdominal distention. The prognosis is poor, and the 3-year survival is less than 30%.²⁹ CT shows multiple large solid intraperitoneal masses (Fig. 111-10) without an apparent primary site. The tumor predominantly involves the omentum and paravesical space. Areas of central low attenuation may correspond to hemorrhage or necrosis. Ascites and hepatic metastases are associated findings. There is both hematogenous and intraperitoneal

Figure 111-10 Desmoplastic small round cell tumor. Patient with desmoplastic small round cell tumor (arrows) demonstrated in the abdomen on axial CT (A), in the pelvis on axial CT (B), and in the abdomen on axial PET/CT (C).

spread that can be seen with this tumor. Retroperitoneal and paratesticular involvement has been reported with this tumor. Malignant ascites is frequently seen with these tumors. They tend to be of low T1 and high T2 signal intensity and demonstrate heterogeneous contrast enhancement.¹

ADENOMATOID TUMOR

This is a very rare tumor that is typically discovered incidentally. Adenomatoid tumor can occur in conjunction with the multicystic mesotheliomas.³⁰ It is typically small and characterized by epithelioid cells.¹

OTHER PRIMARY MESENCHYMAL TUMORS

Tumors may arise from the mesenchymal structures and may be of fatty, vascular, lymphatic, or neurogenic tissue origin.

Tumors of fatty origin can range from benign lipoma to the malignant liposarcoma. Benign lipoma is usually a well-defined homogeneous lesion containing tissue of fat attenuation on CT. Liposarcomas can be ill-defined heterogeneous lesions with a variable soft tissue component (Fig. 111-11). The diagnosis of liposarcoma³¹ can be made on CT if this mass contains fat interspersed with the soft tissue component or areas of enhancement.

Hemangiomas can occur in the mesentery. These are further divided into cavernous, capillary, and venous types. Cavernous hemangiomas containing large vascular sinusoids are the most common type of hemangioma to occur in the mesentery. They are typically of soft tissue attenuation and may contain phleboliths within them.^{32,33} Hemangiopericytomas can also occur in the mesentery and are typically large, vascular masses (Fig. 111-12).

Lymphangiomas are benign tumors of lymphatic origin. These can be either congenital tumors or benign tumors of

mesenchymal origin. They are typically multiloculated cystic masses with thin enhancing walls (Fig. 111-13). It can be difficult to differentiate them from cystic mesotheliomas.³⁴

Tumors of neurogenic origin are typically benign and are more common in the retroperitoneum than in the mesentery. On CT, these tumors are solid low-attenuation masses (Fig. 111-14) that show minimal contrast enhancement.³⁵ They are of low T1 signal intensity and intermediate to high T2 signal intensity and show minimal contrast enhancement. They may

show a tubular or elongated pattern. Uncommonly, they may show malignant degeneration.

Leiomyomatosis peritonealis disseminata is a rare entity characterized by multiple smooth muscle tumor nodules throughout the peritoneum. This is typically found in young women with uterine fibroids and detected incidentally.¹

Sarcomas are more common in the retroperitoneum compared with the mesentery. The tumors often arise in the retroperitoneum and extend into the peritoneum. They are typically large at the time of diagnosis (Fig. 111-15) and can show areas

Figure 111-16 Peritoneal carcinomatosis. Patient with metastatic colon carcinoma who has small peritoneal nodules (arrows) from peritoneal metastases.

of central low attenuation related to necrosis or hemorrhage. Malignant fibrous histiocytoma is the most common peritoneal sarcoma.

Secondary Tumors

The intra-abdominal spread of metastatic disease can occur by (1) direct extension along the mesentery and ligaments, (2) intraperitoneal seeding, (3) lymphatic extension, and (4) hematogenous dissemination.³⁶

Direct extension occurs most commonly in gastrointestinal and pancreatic tumors and can involve the various ligaments surrounding the site of primary tumor. Intraperitoneal seeding is related to the movement of malignant cells within ascitic fluid, thereby being deposited in the peritoneal cavity. Lymphatic dissemination is most commonly seen with lymphoma. Hematogenous metastases typically occur on the antimesenteric border of the bowel loops by distal embolization. This is commonly seen in melanoma and breast and lung carcinoma.

PERITONEAL CARCINOMATOSIS

Peritoneal carcinomatosis is usually seen in tumors arising from the gastrointestinal tract, pancreas, melanoma, breast, lung, and ovary. Any of the four mechanisms listed before can seed the peritoneum, and this can cause peritoneal carcinomatosis. A variable amount of fluid exists in the peritoneal cavity. This circulates from the superior abdomen caudally to the pelvis and then back again to the superior abdomen. Both gravity and respiration play a role in the fluid circulation within the peritoneal cavity. Peritoneal carcinomatosis is manifested on CT as nodularity to the peritoneum (Fig. 111-16), which can progress to peritoneal masses. When the primary tumor is mucinous, such as in appendiceal or ovarian tumors, diffuse peritoneal involvement with cystic implants can be seen (Fig. 111-17). This is called pseudomyxoma peritonei. Detection of

Figure 111-17 Metastatic mucinous appendiceal carcinoma. Axial CT demonstrating mucinous implants causing scalloping of the liver and spleen (arrows) with thin calcifications (A) and with mucinous implants causing mass effect (arrows) on bowel loops (B).

peritoneal carcinomatosis is difficult, especially when the nodules are subcentimeter in size. Peritoneal nodules can often mimic unopacified small bowel loops. Accurate assessment for peritoneal carcinomatosis requires adequate bowel opacification and the intravenous administration of contrast material. The nodules create mass effect on the organs adjacent to them. They can cause scalloping of the liver and spleen; they can cause mesenteric infiltration and thickening, leading to a stellate mesentery; and they can involve the surface of the bowel, causing bowel wall thickening and potentially bowel obstruction. Common sites of involvement include the right hemidiaphragm, right paracolic gutter, cul de sac, and omentum.³⁷

CARCINOID TUMOR

These are rare tumors and represent only 2% of all gastrointestinal tumors. However, carcinoid tumors are the second most common small bowel neoplasm and account for 25% of all small bowel masses.³⁸ They are derived from the enterochromaffin cells; 85% of all carcinoid tumors are found in the gastrointestinal tract. Carcinoid tumors of the gastrointestinal tract are most frequently found in the appendix (50%) and then in the small intestine, primarily the ileum. Metastatic adenopathy involving the mesenteric nodes is seen with small bowel carcinoids. There is intense desmoplastic reaction surrounding the mesenteric mass,³⁹ which can cause radiating strands from the mesenteric mass, rigidity and fixation of the small bowel loops, and sometimes kinking of small bowel loops (Fig. 111-18). The mesenteric fibrosis may also involve mesenteric vasculature and potentially cause mesenteric ischemia. Calcification within the mesenteric mass is seen in 70% of the cases. On MRI, the mesenteric mass is of low T1 signal intensity and intermediate T2 signal intensity and demonstrates evidence of contrast enhancement.

LYMPHOMA

Lymphoma can involve the mesentery, manifested as either enlarged adenopathy or less commonly peritoneal lymphomatosis. Mesenteric involvement by adenopathy is common in non-Hodgkin's lymphoma, occurring in nearly half of these patients (Fig. 111-19). The classic appearance on CT is that of confluent masses that surround the superior mesenteric artery

Figure 111-18 Carcinoid tumor. Axial CT in a patient with metastatic carcinoid tumor of the small bowel to the mesenteric nodes (arrow). This metastatic node causes a desmoplastic reaction with radiating strands into the mesentery.

and vein, producing the sandwich sign.⁴⁰ There is usually associated retroperitoneal adenopathy. Many other disease conditions can be manifested with enlarged mesenteric adenopathy, including metastatic disease and reactive adenopathy from granulomatous infections, acquired immunodeficiency syndrome (AIDS), Crohn's disease, and Whipple's disease.

Peritoneal lymphomatosis is much less common and can mimic peritoneal carcinomatosis (Fig. 111-20) and tuberculous peritonitis.⁴¹ Ascites is commonly seen. Bowel involvement by lymphoma is also often seen as bowel wall thickening or aneurysmal dilation of the bowel. Mesenteric and retroperitoneal enlarged adenopathy is also seen. Peritoneal lymphomatosis is typically seen in high-grade aggressive lymphomas, including small cell, large cell, and lymphoblastic lymphoma. This can mimic aggressive carcinomas.

Inflammatory and Infiltrative Diseases

PANCREATITIS

Acute pancreatitis is an acute and diffuse inflammation of the pancreas. This can range from mild acute pancreatitis to severe acute pancreatitis. Mild acute pancreatitis occurs in 75% to 80% of patients and is characterized by pancreatic interstitial edema and inflammation, which spontaneously resolves without complications. Severe acute pancreatitis is seen in a minority of patients and can be characterized by pancreatic or retroperitoneal fat necrosis and systemic distant organ failure. In the majority of cases, imaging is not necessary. In one third of

patients with pancreatitis, the pancreas may be normal on CT. In the other patients with mild acute pancreatitis, thickening and peripancreatic fat stranding and nodularity can be seen (Fig. 111-21). CT with intravenous administration of contrast material is of help in patients with severe acute pancreatitis and in patients with fevers and leukocytosis. The enhanced CT can help assess the extent of pancreatitis and the presence of peripancreatic fluid collections, hemorrhage, pancreatic or retroperitoneal necrosis, and pancreatic abscess formation. In these patients, the early use of CT has been shown to be beneficial to assess the severity and for follow-up. Peripancreatic fluid collections can dissect through the peritoneum and track along ligaments. They can be seen near the splenic hilum, in the gastrohepatic ligament, along the transverse mesocolon, and along the small bowel mesentery. The colon cutoff sign is seen when the fluid and inflammatory changes track to the transverse colon through the transverse mesocolon, causing an abrupt change in the caliber of the colon at the anatomic junction of the transverse and descending colon.

Figure 111-19 Lymphoma. Patient with lymphoma involving the jejunum with lymphadenopathy (arrows) extending into the small bowel mesentery.

DIVERTICULITIS

Diverticulosis of the colon is a common finding at CT. Diverticulitis of the colon develops in 15% to 30% of all patients with diverticulosis.⁴² This is characterized by thickening of the colonic wall with poor visualization of haustral folds and pericolonic fat stranding (Fig. 111-22). Diverticulitis can also cause colonic perforation, pericolonic abscess formation, fistula formation to adjacent structures, and colonic or ureteral obstruction due to the inflammatory changes.⁴³ These cases account for approximately one fifth of cases, and surgery may be required instead of conservative treatment. CT provides a noninvasive method to assess the extent of diverticulitis and presence of complications and has become the imaging test of choice in diverticulitis. CT also provides a road map for percutaneous drainage procedures for abscess collections. On occasion, perforated colonic neoplasms, pelvic inflammatory disease, endometriosis, and appendicitis can be confused with diverticulitis. Continued follow-up after resolution of acute symptoms is recommended to exclude a primary colonic malignant neoplasm.

Figure 111-20 Peritoneal lymphomatosis. Axial CT (A) and coronal PET/CT (B) demonstrate peritoneal lymphomatosis (arrows). The imaging appearance is similar to that of peritoneal carcinomatosis.

Figure 111-21 Pancreatitis. **A.** Axial CT at the time of acute pancreatitis demonstrates hazy soft tissue (arrow) surrounding the pancreas and extending into the root of the mesentery. **B.** Axial CT obtained 2 months later demonstrates evolution of the changes of pancreatitis with a more solid appearance (arrow).

Figure 111-22 Diverticulitis. Axial CT in a patient with diverticulitis with stranding along the sigmoid colon (arrows).

CROHN'S DISEASE

Crohn's disease, a chronic granulomatous inflammatory disease of the gastrointestinal tract, can occur anywhere from the mouth to the anus. This is of unknown etiology and has a characteristic relapsing and remitting course involving discontinuous portions of the gastrointestinal tract. The small bowel and typically the distal ileum are the most commonly affected sites. CT findings include segmental bowel wall thickening, submucosal edema, and mucosal hyperenhancement in the acute phase.⁴⁴ CT can also show areas of bowel stenosis or narrowing with prestenotic dilation, fibrofatty proliferation surrounding the affected segment (Fig. 111-23), fistulization to adjacent structures, and abscess formation. The fibrofatty proliferation

Figure 111-23 Crohn's disease. Axial CT in a patient with Crohn's disease. CT demonstrates a thickened small bowel loop (arrow) surrounded by normal-appearing small bowel loops.

can result in a marked increase in the amount of fat surrounding an affected bowel loop or in increased density of the fat due to inflammation. Fistulization can occur to adjacent bowel loops but occasionally can occur to the skin. Internal fistulization can occur in 15% to 40% of patients with active disease. Enlarged mesenteric adenopathy, especially involving the ileocolic nodes, can be seen in Crohn's disease. CT can be beneficial in assessing complications and monitoring therapy.

MR enterography is being increasingly used in young adults with Crohn's disease. The advantages of MRI include repeated imaging without unnecessary radiation; real-time imaging to assess fixed small bowel loops; and diffusion-weighted imaging, which can highlight areas of restricted diffusion thought to be arising from acute inflammation.^{45,46}

MESENTERIC PANNICULITIS OR SCLEROSING MESENTERITIS

This has various names, including retractile mesenteritis, mesenteric lipodystrophy, and xanthogranulomatous mesenteritis.⁴⁷ It is a rare condition of unknown etiology that is characterized by mesenteric inflammation, fibrosis, and variable amounts of fat necrosis. This is often associated with other inflammatory conditions, such as retroperitoneal fibrosis, sclerosing cholangitis, Riedel thyroiditis, orbital pseudotumor, and more recently along the spectrum of the immunoglobulin G4-elevated sclerosing disorders.⁴⁸ This has a wide age range with the peak incidence in the sixth and seventh decades and a male-to-female ratio of 1.8 to 1. Criteria for diagnosis require exclusion of pancreatitis, inflammatory bowel disease, and extra-abdominal fat necrosis, such as Weber-Christian disease. This typically involves the small bowel mesentery, especially at the root of the mesentery.

Common clinical symptoms include abdominal pain, weight loss, fever, nausea, vomiting, intestinal obstruction, and mesenteric ischemia. This condition may be manifested predominantly in one of three ways: mesenteric panniculitis, which is characterized by chronic inflammation and subtle increased density of the mesenteric fat; mesenteric lipodystrophy, which is characterized by fat necrosis; and retractile mesenteritis, which is characterized by fibrosis. Patients may present with all three manifestations.

On upper gastrointestinal and barium enema examinations, there is displacement of the bowel loops by a mesenteric mass, with the jejunal mesentery being most commonly involved. The bowel loops may be dilated, fixed, or narrowed, but complete obstruction is rare. On CT, the findings can vary from slightly increased density of the mesenteric fat to a spiculated soft tissue mass (Figs. 111-24 and 111-25). The soft tissue masses in this condition can cause intestinal obstruction and can infiltrate around mesenteric vessels to cause ischemia. There may be a small rim of fat preserved around the vessels called the fat ring

or halo sign, which may help in the diagnosis. On occasion, the area of mesenteritis can show areas of central calcification. Differential diagnosis includes carcinoid metastases to the mesentery and lymphoma. The finding of increased density of mesenteric fat on CT has a wide differential and is presented in Box 111-1.

TUBERCULOSIS

Tuberculous peritonitis occurs in less than 4% of patients with tuberculosis and has been described as the sixth most common site of extrapulmonary tuberculosis.⁴⁹ This is most commonly due to hematogenous dissemination, but ruptured involved bowel, nodes, or fallopian tubes may occasionally be the cause. As many as 80% of the cases of abdominal tuberculosis are now associated with underlying immunodeficiency.⁵⁰

This has been classified further into the wet, fixed and fibrotic, and dry plastic types. The wet type is the most common presentation (90%) and consists of large amounts of ascites (free flowing or loculated). The fixed fibrotic type is the next most common and is characterized by omental and mesenteric masses with fixed and matted bowel loops. The dry type is characterized by a fibrous thickening of the peritoneum and caseous lymph nodes.⁵⁰ There is often overlap between these three types.

The lymphadenopathy is typically found in the mesenteric and peripancreatic locations rather than retroperitoneally because of involvement of the small bowel and liver. The classic appearance is of rim-enhancing centrally necrotic nodes, likely related to caseous necrosis. The ascites is typically of high attenuation ranging between 20 and 45 HU due to the high cellular and protein content. Other findings that support the diagnosis include hepatosplenomegaly with focal hepatic and splenic lesions, peritoneal enhancement, and bowel involvement. Assessment of the bowel, especially in the ileocecal region, may

further help with the diagnosis. Early diagnosis and treatment are crucial because of the high mortality rates.⁵⁰

WHIPPLE'S DISEASE

Whipple's disease is a rare multisystem infection caused by a gram-positive bacillus, *Tropheryma whipplei*. It affects multiple organs. There is abnormal accumulation of lipid-laden macrophages, which contain bacterial elements that stain with the periodic acid-Schiff method. These macrophages accumulate mainly in the submucosa of the small bowel. Clinical symptoms include weight loss, abdominal pain, arthralgias, and steatorrhea. Small bowel fold thickening is noted along with enlarged low-attenuation mesenteric nodes. The fold thickening is likely to be related to a combination of macrophage deposition and dilated lymphatics from nodal involvement. Enlarged low-attenuation mesenteric nodes, which can cause lymphatic stasis

and secondary bowel thickening, are typically seen. Enlarged nodes can be seen in the peripancreatic, retroperitoneal, and occasionally mediastinal locations.

The low attenuation of these nodes is characteristic for Whipple's disease.⁵¹ The differential diagnosis for low-attenuation nodes includes metastatic disease, such as treated testicular cancer, treated lymphoma, and tuberculosis.

AMYLOIDOSIS

Systemic amyloidosis is caused by the extracellular deposition of amyloid in an abnormal fibrillar form in multiple organs. This may occur as a primary process or secondary to a number of chronic diseases and can occur in multiple myeloma. Clinical symptoms and signs include bowel obstruction, pseudotumor, hepatomegaly, and macroglossia. The amyloid deposition can lead to bowel wall thickening and rarely to mesenteric and omental soft tissue infiltration. Discrete nodules and coarse dystrophic calcification within the involved peritoneum can be seen on CT. Mesenteric and retroperitoneal lymphadenopathy can also be seen.^{52,53}

EXTRAMEDULLARY HEMATOPOIESIS

Extramedullary hematopoiesis refers to conditions in which there is a compensatory response to decreased hematopoiesis (as in myelofibrosis) or in the presence of a hemoglobinopathy (such as thalassemia). The predominantly affected regions are the liver, spleen, and paraspinal soft tissues. Rarely, the mesentery and peritoneum may be involved. On CT, this is manifested as large soft tissue masses within the mesentery and peritoneum, with minimal mass effect on adjacent structures such as the bowel.⁵⁴ Differential diagnosis includes lymphoma.

TRAUMA AND HEMORRHAGE

Mesenteric hemorrhage is unusual but can be seen in blunt abdominal trauma, aneurysm rupture, anticoagulation, and thrombocytopenia. Acute hemorrhage can be dense (between 50 and 60 HU) on noncontrast CT,⁵⁵ which can decrease in attenuation during 2 weeks. Barium studies may demonstrate displacement of bowel loops and bowel wall thickening if there is bowel wall hemorrhage. On ultrasound, there can be a variety of appearances, depending on the age of the hemorrhage. Similarly, on MRI, there can be a variety of appearances on the basis of the age of the hemorrhage. Most acute hemorrhages have a high T1 signal intensity. Approximately 50% of the significant hemorrhages that occur with anticoagulation occur intra-abdominally and can involve bowel wall, retroperitoneum, and the abdominal wall.

MESENTERIC EDEMA

Mesenteric edema can be caused by conditions including systemic hypoalbuminemic states, such as cirrhosis or nephrotic syndrome, and lymphatic or venous obstruction. The typical finding on CT is diffuse increased hazy density of the fat of the mesentery and indistinctness of vessels within the mesentery. The term *misty mesentery*, used by Mindelzun and colleagues,² is often the sign of underlying mesenteric disease and is associated with an increase in the density of the fat in the mesentery. This is a nonspecific sign and can be seen in mesenteric edema,

hemorrhage, trauma, inflammation, and tumor involvement as shown in [Box 111-1](#). Careful assessment of the larger mesenteric veins for venous thrombus and venous obstruction related to a mass should be performed. In systemic conditions causing the mesenteric edema, subcutaneous and bowel wall edema can also be seen.

MESENTERIC CYSTS

Cystic lesions in the mesentery may be duplication cysts, enteric cysts, lymphangiomas, pseudocysts, teratomas, and mesothelial cysts.^{56,57} These are frequently congenital and benign lesions.

Lymphangiomas are multilocular cystic lesions with rim enhancement. The different locules may contain complex fluid. These can be adherent to adjacent bowel, necessitating bowel removal at the time of resection. Pseudocysts can be seen in patients with a prior history of pancreatitis ([Fig. 111-26](#)). They can be unilocular or multilocular and have a distinct wall. The wall typically shows contrast enhancement. They can demonstrate echogenic debris on ultrasound. Enteric duplication cysts also typically have thick walls ([Fig. 111-27](#)) compared with enteric cysts, which have a thin wall. Benign cystic mesotheliomas are also in the differential.

Omentum

The anatomy of the omentum is discussed earlier. The omentum also contains vessels and lymphatics along with areolar tissue, just like the other peritoneal folds. In addition to storing fat, the omentum plays an important role in walling off infections and scavenges inflammatory and neoplastic cells in the peritoneal cavity. The arterial supply is from branches of the celiac axis, and the venous drainage is through the splenic and superior mesenteric veins into the portal vein. Whereas the greater

omentum helps minimize the spread to transdiaphragmatic lymph channels, this may increase the spread to the portal circulation and liver.

RADIOLOGIC FEATURES

Plain abdominal radiographs rarely depict omental disease. In cases of large omental masses, secondary signs related to displacement of bowel loops may help make the diagnosis. Indirect evidence of omental infiltration on barium enema studies may be inferred by mass effect, tethering of folds, or luminal narrowing, especially along the superior border of the transverse colon.

Ultrasound may be of help in patients with large omental masses, but distinguishing smaller masses from bowel loops may be difficult. Ultrasound is also operator dependent, making reproducibility and assessment of response difficult.

The most commonly used imaging modality in assessment of omental and peritoneal disease is CT. With the advent of multidetector CT (MDCT), thinner slices and rapid speed of imaging have improved detection of small omental and peritoneal nodules. Optimal bowel contrast opacification is critical in imaging of patients with suspected omental and peritoneal disease. Lack of intra-abdominal fat may make the visualization of the omental disease difficult.

The normal greater omentum is routinely identified as a homogeneous fat-attenuating structure anterior to and lateral to the transverse colon. This should be distinguished from the more centrally located small bowel mesentery. The omentum is typically affected secondarily in disease processes such as peritoneal carcinomatosis and can be involved in inflammatory processes that affect the peritoneum and the adjacent organs. Primary omental disease is rare and may be seen with omental cysts, segmental infarction, torsion, and primary omental tumors.

Figure 111-26 Pseudocyst. Axial CT demonstrating a pseudocyst (Ps, arrow) near the pancreas (P).

Figure 111-27 Enteric duplication cyst. Axial CT demonstrating a thick-walled enteric duplication cyst (arrows).

PRIMARY NEOPLASMS

Primary omental neoplasms are rare and can include tumors of mesenchymal origin, such as lipoma/liposarcoma, lipoblastoma, fibroma/fibrosarcoma, and leiomyoma/leiomyosarcoma.⁵⁸ Teratomas and hemangioblastomas of the omentum have also been described. Symptoms occur late in the course of disease and are nonspecific and may be related to abdominal bloating and pain. Approximately 33% of omental masses are malignant. The CT appearance for omental masses is often nonspecific. The presence of fat within the mass may further narrow the differential diagnosis to masses that contain fat, such as lipoma, lipoblastoma, and liposarcoma, and other non-neoplastic conditions, such as panniculitis, focal infarction, and torsion.

METASTATIC DISEASE AND LYMPHOMA

Metastatic disease is the most common cause of omental lesions. The metastatic cells can implant on the surface of the omentum and invade through the loosely bound basement membrane to proliferate in the omental fat. Omental infiltration favors a diagnosis of tumor involvement and usually indicates peritoneal involvement. The classic “omental cake” is from complete replacement of the omentum by tumor involvement ([Fig. 111-28](#)). On CT, a thick soft tissue mass is seen replacing the entire omentum and is located anterior to the transverse colon. This soft tissue mass can extend down into the pelvis also. The early manifestations of omental involvement on CT can begin as small areas of nodularity and fat stranding. Detection of small omental implants has improved with MDCT but still remains a challenge. Assessment for secondary signs of peritoneal involvement, such as ascites, may also be of help.

Ovarian cancer is the most frequent cause of metastatic disease to the omentum. Omental involvement is found at the time of initial laparotomy and is almost universally present at

autopsy. Although an abnormal-appearing omentum in a patient with ovarian cancer is strongly indicative of metastatic disease, a normal-appearing omentum on CT does not exclude involvement.⁵⁹ Tumors that commonly spread to the omentum include carcinomas of the colon, stomach, pancreas, breast, and endometrium and adenocarcinomas of unknown primary site.⁵⁸ Melanomas, sarcomas, and lymphomas can also involve the omentum. Calcified omental masses generally indicate tumors of mucinous origin, such as ovarian and colon tumors. Leiomyosarcomas typically tend to produce large, well-defined soft tissue masses in the omentum with areas of central necrosis.

INFLAMMATORY DISEASES

Pancreatitis

Inflammation from pancreatitis typically involves the peripancreatic fat, adjacent retroperitoneum, and lesser sac and can extend to involve the small bowel mesentery. In severe cases, the inflammation may extend to the colon and greater omentum. Omental changes, such as stranding and infiltration phlegmonous changes, pseudocyst and abscess formation, and occasionally ascites, can occur.

Tuberculosis

The CT appearance of tuberculous peritonitis can be indistinguishable from that of peritoneal carcinomatosis with omental nodularity, caking, and ascites. Centrally low attenuation, enlarged nodes may help narrow the differential diagnosis. Hepatosplenomegaly is an associated finding seen in tuberculosis. In patients with risk factors, tuberculous peritonitis should be considered because of the high mortality associated with this condition.

Panniculitis

Idiopathic panniculitis is inflammation of the fat in the omentum. The CT findings include increased density and stranding surrounding the omentum. The changes are identical to those observed in the small bowel mesentery, where they are more common.

MISCELLANEOUS CONDITIONS

A variety of other processes affect the omentum. These include traumatic hematoma, omental hernias, omental infarction, and torsion. Primary segmental infarction often involves the free edge of the right lateral omentum.⁶⁰⁻⁶³ Right lower quadrant pain mimicking appendicitis or cholecystitis can be the presenting symptom. This typically involves young adults (20 to 40 years old), and men are affected twice as commonly as women. The diagnosis on CT is suggested by the presence of focally infiltrated omental fat in the right lower quadrant with a normal-appearing appendix and gallbladder and associated complex intraperitoneal fluid. Omental torsion can be suggested in patients with acute abdominal pain if the CT findings show a fatty mass with fine concentric or swirling lines in the anterior abdomen.

In summary, peritoneal and omental disease may show a wide spectrum of findings on imaging studies. CT and MDCT are currently the most effective radiologic imaging modalities for detection and characterization of pathologic processes involving these areas. The specific feature and distribution of disease can often lead to a precise diagnosis.

Miscellaneous Conditions

Conclusions

Abdominal hernias are commonly encountered in clinical practice, and they account for approximately 750,000 operations per year in the United States.¹ Most herniations involving the anterior abdominal wall or groin can be easily diagnosed by inspection and palpation. In these cases, the radiologic examinations are useful for preoperative demonstration of the hernia's contents and associated complications, such as bowel obstruction or ischemia. Diagnostic radiology is the principal means of detecting the internal, diaphragmatic, and other nonpalpable or unsuspected hernias.²⁻⁷

Multidetector computed tomography (MDCT) can show several features of hernias that are critical to diagnosis and management: the precise anatomic site of the hernia sac; the shape of the sac and its connections; the contents of the sac; the hernia cuff and surrounding wall; and complications of the intestinal, vascular, omental, and mesenteric wall and cavity of the hernia sac. The multiplanar capabilities of MDCT offer exquisite detail of the anterior abdominal and pelvic wall. It can identify wall hernias and their contents, detect postoperative complications, and characterize hematomas, abscesses, and neoplasms.

This chapter describes the clinical and radiologic features of various abdominal herniations. In many instances, small and reducible hernias are discovered incidentally during gastrointestinal barium studies or CT of the abdomen performed to investigate unrelated conditions.²⁻⁷ Asymptomatic hernias do not warrant surgical repair, but their presence should always be brought to the attention of the patient and the referring physician. If intestinal obstruction attributable to an incarcerated

hernia develops at a future time, it can then be treated without undue delay while the underlying cause is sought.

Hernia Classification

Abdominal hernias can be classified as three major types. *Internal hernia* denotes protrusion of gut through a peritoneal or mesenteric aperture of omentum, mesentery, or peritoneal ligament, leading to its encapsulation within another compartment of the otherwise intact abdominal cavity. An *external hernia* (i.e., abdominal wall hernia) is caused by prolapse of an intestinal loop, omentum, or mesentery through a defect in the wall of the abdomen or pelvis. Diaphragmatic hernias, in which gut, omentum, or mesentery herniates into the chest, are usually considered a separate category.

The responsible hernia orifice is often a preexisting anatomic structure, such as the epiploic foramen of Winslow, inguinal canals, or esophageal hiatus. Pathologic defects of congenital, postsurgical, or traumatic origin are also potential sites of herniation.¹⁻⁷ Mobile segments of the small or large bowel are usually the content of abdominal hernias, but the greater omentum and various other viscera or pelvic organs are occasionally involved.

The nomenclature used for specific hernias indicates the anatomic location of their orifice rather than the nature of the protruding organ. The classification is therefore based on topographic distribution of the relatively common types of hernias (Box 112-1).

Hernias

INTERNAL ABDOMINAL HERNIAS

The autopsy incidence of internal hernias is in the range of 0.2% to 0.9%.^{2,4} They are becoming more common with increasing use of bariatric surgery and liver transplantation. Figure 112-1 shows their typical location.² Internal hernias may remain clinically silent if they are easily reducible, but the larger ones often cause vague epigastric discomfort, colicky periumbilical pain, and recurrent episodes of intestinal obstruction. Physical examination may reveal a palpable mass of herniated loops with localized tenderness. In these patients, the correct diagnosis can be made if barium study or CT of the abdomen is performed during the symptomatic periods. Otherwise, the hernia may not be recognized after it is reduced spontaneously or after bowel decompression with a nasogastric tube.

By far, the most common presentation of an incarcerated internal hernia is acute small bowel obstruction. In a large series of patients who underwent operation for bowel obstruction, the

In Yoshida O [ed]: *Anatomy for Urologic Surgery*, Tokyo, 1998, Medical View, pp 114–133.)

underlying causes proved to be internal hernia (4.1%), external hernia (17.5%), neoplasms (18%), or adhesions (32%).⁸

Each type of internal hernia has specific radiologic features (Table 112-1), which are described later in this chapter. As a general rule, barium studies and CT show certain diagnostic hallmarks shared by various internal hernias, including abnormal location of an intestinal segment in susceptible regions, such as the lesser sac; encapsulation and crowding together of several small bowel loops within the confines of the peritoneal cavity; stasis of contrast material in the lumen and dilation of more proximal bowel; and apparent fixation of the herniated loops, preventing their separation or dislodgment during fluoroscopic manipulations or by changing the position of the patient.^{2,4}

Preoperative radiologic diagnosis or a high index of suspicion for an internal hernia is important because at laparotomy, spontaneous reduction or inadvertent traction of the herniated loops may cause it to be overlooked. The usual abdominal exploration is inadequate for evaluating all peritoneal fossae and mesenteric defects that could serve as potential sites of herniations.^{2,4}

Paraduodenal Hernia

Paraduodenal hernias are the most common type of intra-abdominal herniation, and they account for 53% of the reported cases.^{2,9-13} They are more common in men than in women, with a ratio of about 3:1. Approximately 75% occur on the left and involve the paraduodenal fossa of Landzert. This peritoneal pocket is observed at 2% of autopsies. It is located just lateral to the ascending, or fourth, segment of the duodenum, beneath a peritoneal fold elevated by the inferior mesenteric vein and ascending left colic artery. Small bowel loops enter the sac from behind, where the duodenum emerges from its fixed retroperitoneal position. They protrude farther posteriorly and to the left, essentially herniating into the descending mesocolon and distal portion of the transverse mesocolon.^{2,4}

Twenty-five percent of paraduodenal hernias develop on the right side of the abdomen and typically involve the mesentericoparietal fossa of Waldeyer. This abnormal pocket in the jejunal mesentery is found at 1% of autopsies. Its orifice is located immediately behind the superior mesenteric artery and inferior to the transverse segment of the duodenum; however, the peritoneal pocket itself extends to the right and downward, directly in front of the posterior parietal peritoneum. Accordingly, the right paraduodenal hernia can be viewed as small bowel herniation into the ascending mesocolon.^{2,4,9}

The clinical manifestations of paraduodenal hernias range from intermittent and mild digestive complaints to acute

TABLE
112-1

Clinical and Imaging Findings for Internal Hernias

Hernia Type	Subtype	Incidence*	Characteristic Clinical Findings	Radiography and Barium Studies	CT Findings	Key Vessel
Left paraduodenal	Congenital, normal aperture	40% of all hernias, 75% of paraduodenal hernias	Postprandial pain, may date back to childhood	Encapsulated cluster of the jejunum in LUQ, lateral to the ascending duodenum; may have mass effect, indenting the posterior wall of stomach or displacing the transverse colon inferiorly	Clustered dilated small bowel loops between the stomach and pancreas, behind the pancreas itself, or between transverse colon and left adrenal gland	IMV in the neck of the hernia sac with anterior upward displacement of the IMV
Right paraduodenal	Congenital, normal aperture	13% of all hernias, 25% of paraduodenal hernias	Postprandial pain, may date back to childhood	Encapsulated loops lateral and inferior to the descending duodenum; associated with small bowel nonrotation	Encapsulated loops lateral and inferior to the descending duodenum; associated with small bowel nonrotation	SMA displaced anteriorly
Pericecal	Congenital or acquired, abnormal aperture	13%	RLQ pain, differential diagnosis of appendicitis; high incidence of occlusive symptoms	Clustered small bowel loops (usually distal) posterior and lateral to the cecum in the right paracolic gutter	Clustered small bowel loops (usually distal) posterior and lateral to the cecum in the right paracolic gutter	None
Foramen of Winslow	Congenital, normal aperture	8%	Symptoms of proximal obstruction because of mass effect on stomach; symptom onset often preceded by changes in intra-abdominal pressure (i.e., parturition, straining); relief of symptoms with forward bending	Circumscribed loops medial and posterior to the stomach; differential diagnosis of cecal volvulus	Loops in the lesser sac between the liver hilum and IVC	None; vessels stretched through the foramen of Winslow
Intersigmoid	Type 1: congenital, normal aperture Types 2 and 3: acquired, abnormal aperture	6%	None	U- or C-shaped cluster of small bowel posterior and lateral to the sigmoid colon	U- or C-shaped cluster of small bowel posterior and lateral to the sigmoid colon	None
Transmesenteric [†]	In children: congenital, abnormal aperture In adults: usually acquired, abnormal aperture	8%	Two typical patient populations: children and postsurgical adults In adults, less vomiting because fewer secretions in proximal gastric pouch, onset more acute	Variable, air within gastric remnant; may simulate a left paraduodenal hernia	Small bowel lateral to the colon; displaced omental fat with small bowel directly abutting the abdominal wall	None
Retroanastomotic [†]	Acquired, abnormal aperture	5%	Usually within the first postoperative month; less vomiting because fewer secretions in the proximal gastric pouch	Variable	Variable	None

*Incidences for the first six types are from Meyers¹¹²; they are historic data but are the only major source available. Incidences for these first six types of internal hernias total only 93% because the perivesical hernias reported¹¹² are not true internal hernias, so they were not included in this review.

[†]Probably more transmesenteric and retroanastomotic internal hernias currently because of the number of liver transplantations and gastric bypass operations being performed throughout the United States during the past decade. The 5% refers to the incidence after Roux loops were used during surgery for reasons other than liver transplantation or gastric bypass.

IMV, inferior mesenteric vein; IVC, inferior vena cava; LUQ, left upper quadrant; RLQ, right lower quadrant; SMA, superior mesenteric artery.

intestinal obstruction. Recurrent periumbilical cramps or postprandial epigastric pain and distention are frequently experienced before the onset of incarceration.^{2,9} Contrast examinations of the gastrointestinal tract are most likely to provide the correct diagnosis during symptomatic periods. After the hernia is reduced spontaneously, however, results of barium studies tend to be negative, and the patient may be mislabeled as psychoneurotic.

The characteristic radiographic features of left paraduodenal hernias have been described by several investigators.^{2,4,5,9-12} A circumscribed, ovoid mass of multiple jejunal loops occupies the left upper quadrant immediately lateral to the ascending duodenum (Fig. 112-2). The hernia indents the posterior gastric wall and depresses the distal transverse colon. Fluoroscopy and serial radiographs reveal a separation of encapsulated loops from the remaining small intestine. Dilatation of the involved segments and stasis of barium may also be evident. Because the duodenum is retroperitoneal and the herniated proximal jejunal

loops enter the fossa of Landert posteromedially, only one loop of distal small intestine exits through the hernia orifice. The inferior mesenteric vein and ascending left colic artery lie in the anteromedial border of the left paraduodenal hernia.^{2,4,9} These findings are best appreciated during laparotomy, but CT scans of the upper abdomen may help demonstrate them before operation.

Right paraduodenal hernias are manifested as a similar ovoid grouping of several small bowel loops just lateral and inferior to the descending duodenum (Fig. 112-3). They are usually more massive and fixed than those on the left side. Afferent and

Figure 112-2 Left paraduodenal hernia. **A.** Graphic illustration of a left paraduodenal hernia depicts loop of small bowel prolapsing (curved arrow) through Landert's fossa, located behind inferior mesenteric vein and ascending left colic artery (straight arrow). Herniated bowel loops are therefore located lateral to the fourth portion of the duodenum. **B.** Axial CT scan shows a closed loop obstruction of a short segment of proximal jejunum (arrows). The mural thickening and mesenteric edema suggest superimposed ischemia. (A from Martin LC, Merkle EM, Thompson WM: Review of internal hernias: Radiographic and clinical findings. *AJR Am J Roentgenol* 186:703-717, 2006. Figure 112-3 Right paraduodenal hernia. **A.** Graphic illustration of right paraduodenal hernia shows loop of small bowel prolapsing (arrow) through Waldeyer's fossa, behind superior mesenteric artery and inferior to third portion of duodenum (asterisk). **B.** Axial CT scan shows a cluster of jejunal loops (arrow) in a closed loop obstruction. Note the poor mural enhancement and edema in the adjacent mesentery, indicating ischemia. (A from Martin LC, Merkle EM, Thompson WM: Review of internal hernias: Radiographic and clinical findings. *AJR Am J Roentgenol* 186:703-717, 2006. Reprinted with permission from the American Journal of Roentgenology.)

effluent intestinal loops pass through the hernia orifice, where they are closely apposed and narrowed.^{2,4,5,7,13} Lateral radiographs are particularly useful for demonstrating the retroperitoneal displacement of the hernia contents. Barium enema examination shows that the ascending colon lies lateral to a right paraduodenal hernia, and the cecum retains its normal position.

The superior mesenteric artery and its ileocolic branches are situated in the anterior wall of the right paraduodenal hernia sac. The passage of herniated loops behind these vessels causes arteriographically detectable changes.² The jejunal arteries, which normally arise from the left side of the superior mesenteric artery, abruptly reverse direction to the right and course behind the parent vessel to supply the herniated loops in the fossa of Waldeyer.

Operative techniques for the correction of paraduodenal hernias are described elsewhere.⁹ Preoperative diagnosis and demonstration of their radiographic anatomy assist the surgeon to better understand the extremely confusing laparotomy findings. Blind division of the hernia sac should be avoided because it carries the risk of injury to the vital mesenteric vessels contained within its wall. It may create a mesenteric defect that could later serve as a potential site for an iatrogenic internal hernia.^{2,4}

Foramen of Winslow Hernia

The lesser sac communicates with the greater peritoneal cavity through the epiploic foramen of Winslow. This small opening can serve as a pathway for protrusion of viscera into the lesser sac, where 8% of all internal hernias occur.^{2,4-7,14} The small intestine is the herniated segment in 60% to 70% of cases. The terminal ileum, cecum, and ascending colon are involved in about 25% to 30%. The transverse colon, gallbladder, and omentum account for the remainder. Predisposing factors include an enlarged foramen of Winslow and excessively mobile intestinal loops because of a long mesentery or persistence of the ascending mesocolon. Herniation into the lesser sac may be provoked by a sudden increase in intra-abdominal pressure, like that experienced while lifting heavy weights or during parturition. An elongated right lobe of the liver can also be a contributing factor by directing the mobile intestinal loops toward the foramen of Winslow.

This type of internal hernia usually affects middle-aged patients and is manifested as progressive upper abdominal pain and acute onset of small bowel obstruction. Physical examination usually reveals localized tenderness and distention in the epigastric regions. A helpful sign is the relief of pain with forward bending or in the knee-chest position.

Several radiologic features of hernias through the foramen of Winslow are characteristic:

1. Plain radiographs of the abdomen show bowel loops containing gas within the lesser sac medial and posterior to the stomach, usually in conjunction with markedly dilated proximal small intestine. The right iliac fossa may appear empty if the cecum and ascending colon are the herniated segments.^{2,4,5}
2. Upper gastrointestinal examination demonstrates displacement of the stomach to the left and anteriorly because of extrinsic compression by the mass of herniated loops in the lesser sac. The first and second portions of the duodenum may be compressed and deviated to the left side.

3. Small bowel series show dilation and hyperperistalsis of the intestinal loops that indicate distal mechanical obstruction. Serial radiographs and fluoroscopy can localize the site of obstruction to the right upper abdomen, corresponding to the anatomic location of the foramen of Winslow between the duodenal bulb and the hilum of the liver.
4. If the herniation involves the cecum and ascending colon, barium enema examination may reveal a tapered narrowing or obstruction near the hepatic flexure.^{2,4}
5. CT scans of the abdomen show an aberrant position of the bowel loops between the liver, the stomach, and the pancreas (Fig. 112-4). CT is the optimal imaging technique to demonstrate the presence and content of herniations involving the lesser sac.^{5-7,14}
6. Gallbladder herniation into the lesser sac can be diagnosed when the opacified gallbladder appears elongated and its fundus is malpositioned on the left, indenting the gastric antrum or body of the pancreas. Manual compression of the epigastrium can reduce the hernia if the foramen of Winslow is widely patent. Gallbladder strangulation and perforation in the lesser sac may occur if the condition is not diagnosed and treated promptly.¹⁵

Besides the foramen of Winslow, there may be other openings for herniation into the lesser sac. For instance, a defect in the gastrohepatic ligament forming the anterior wall of the lesser sac may follow partial gastrectomy. A congenital or acquired defect may also be present in the transverse mesocolon or gastrocolic ligament, which constitutes the floor of the lesser sac. The intestinal loops can prolapse through these openings to occupy the lesser sac or reenter the greater peritoneal cavity by the foramen of Winslow.^{2,4,16,17}

Pericecal Hernia

Four peritoneal fossae located in the ileocecal region as well as congenital and acquired defects in the mesentery of the cecum or appendix may lead to development of a pericecal hernia.^{2,4,5} The various other terms used to classify these hernias (e.g., ileocolic, retrocecal, ileocecal, paracecal) appear to have limited practical value for radiologic differential diagnosis and surgical management.

In a collective review of 467 cases of internal hernia, 13% involved the ileocecal region.² The clinical manifestations are usually intermittent episodes of colicky right lower abdominal pain associated with small bowel distention, nausea, and vomiting. Chronic incarceration may produce symptoms compatible with periappendiceal abscess, regional enteritis, or intestinal obstruction caused by adhesions.

In most cases, an ileal segment herniates through a defect in the mesentery of the cecum and occupies the right paracolic gutter. The correct diagnosis may be suggested on plain radiographs of the abdomen (Fig. 112-5), provided the unusual relationship of the ileum to the cecum is recognized in association with small bowel obstruction. More useful are delayed radiographs of a small bowel series or a barium enema examination with retrograde opacification of the terminal ileum. Careful fluoroscopic evaluation and filming in lateral and oblique projections are particularly valuable for the demonstration of the fixed position of the herniated ileal loop posterolateral to the cecum.

A. Graphic illustration of foramen of Winslow hernia shows bowel about to prolapse (arrow) into lesser sac, behind hepatoduodenal ligament, the free edge of the lesser omentum.
B. CT scan shows small bowel (arrows) herniated into the lesser sac, causing a closed loop obstruction.
C. Scan obtained several hours later shows that these loops have become ischemic and hemorrhagic. (**A** from Martin LC, Merkle EM, Thompson WM: Review of internal hernias: Radiographic and clinical findings. *AJR Am J Roentgenol* 186:703-717, 2006. Reprinted with permission from the American Journal of Roentgenology.)

Intersigmoid Hernia

Intersigmoid hernias involve the intersigmoid fossa, a peritoneal pouch located between the two loops of the sigmoid colon and its mesentery. This pocket is found at 65% of autopsies.^{2,4,5,18}

Intersigmoid hernias are usually reducible and are an incidental finding during laparotomy. Radiologic diagnosis is best made on barium enema studies in which retrograde filling of the small bowel has been achieved. The examination typically shows a portion of jejunum or ileum to be encapsulated between the sigmoid loops (Fig. 112-6).

In this context, two similar entities deserve a brief mention:

1. In *transmesosigmoid hernias*, a defect involving both layers of the sigmoid mesentery allows herniation of the small bowel loops toward the left lower abdomen, posterolateral to the sigmoid colon. The hernia ring is usually a long slit whose fibrous edge is bound by branches of the inferior mesenteric vessels.^{2,19}
2. In *intramesosigmoid hernia*, a congenital defect may be present in only one of the constituent leaves of the sigmoid mesentery. The small bowel loops passing through this orifice are incarcerated in a hernia sac, which is formed by separation of medial and lateral leaves of the mesosigmoid.^{4,18}

Radiologic differentiation of these three types of hernias involving the mesosigmoid is often difficult, and in terms of their ultimate surgical management, it is irrelevant.

Transmesenteric Hernia

Approximately 5% to 10% of all internal hernias occur through defects in the mesentery of the small bowel. They have no limiting sac, but their functional significance is similar to that of true internal hernias.^{4,19-23}

Almost 35% of transmesenteric hernias affect the pediatric age group, in which they constitute the most common type of internal herniation. The underlying mesenteric defects are usually 2 to 5 cm in diameter and located close to the ligament of Treitz or the ileocecal valve.^{2,4} A causal relationship to prenatal intestinal ischemic accidents seems likely because such mesenteric apertures and associated hernias are frequently found in infants with atretic bowel segments. In adults, however, most mesenteric defects are probably the result of previous gastrointestinal operations, abdominal trauma, or intraperitoneal inflammation.^{2,4,24}

In the absence of a limiting hernia sac, a considerable length of small intestine may protrude through the mesenteric aperture. Volvulus may further complicate the process and cause rapid strangulation and intestinal gangrene.²⁰⁻²⁴ Patients present with severe periumbilical cramps accompanied by hyperactive bowel sounds and progressive distention. A tender abdominal mass, representing the Gordian knot of herniated intestine, may be palpable. Plain radiographs of the abdomen demonstrate a mechanical small bowel obstruction and occasionally show a single, distended closed loop (Fig. 112-7). Small bowel examination may disclose a constriction around the closely approximated afferent and efferent limbs of the herniated intestine. The superior mesenteric arteriogram shows abrupt angulation and displacement of the visceral branches as they pass through the mesenteric defect to supply the herniated loops.²² These findings signal a surgical emergency, although clinical and radiologic differentiation of the mesenteric hernia from other closed loop obstructions (e.g., small bowel volvulus or entrapment beneath peritoneal adhesions) may be impossible.²³⁻²⁵

Defects in the mesenteric attachments of the colon are also the potential sites of internal herniation. For example, a congenital or postsurgical opening in the transverse mesocolon

Figure 112-5 Pericecal hernia. **A.** Diagram of a pericecal hernia shows a loop of ileum prolapsing (arrow) through cecal mesenteric defect, behind and lateral to the cecum, into right paracolic gutter. **B.** CT scan shows small bowel loops (arrows) lateral to the proximal ascending colon. (A from Martin LC, Merkle EM, Thompson WM: Review of internal hernias: Radiographic and clinical findings. *AJR Am J Roentgenol* 186:703-717, 2006. Reprinted with permission from the American Journal of Roentgenology.)

permits small bowel loops to herniate into the lesser sac.^{2,4} A somewhat similar situation can be present in cases of congenital persistence of descending mesocolon. A defect in this structure may allow small bowel herniation into the left paracolic gutter, causing medial displacement of the descending colon.

Transomental Hernia

Approximately 1% to 4% of internal hernias occur through defects in the greater omentum.^{2,4,8} Fewer than 100 cases have been reported from observations made at surgery or autopsy. The hernia orifice is usually a slitlike opening up to 10 cm long, located in the periphery of the greater omentum. Most have a congenital origin, but trauma and inflammation may also produce omental perforations or weak areas. These defects can subsequently serve as potential sites for transomental herniation of the small intestine (Fig. 112-8) and other mobile segments, such as the cecum or sigmoid colon. The clinical and radiologic findings are almost identical to those of transmesenteric hernias.¹⁸⁻²³

Figure 112-6 Intersigmoid hernia. **A.** Illustration of an intersigmoid hernia shows bowel protruding (arrow) through defect in sigmoid mesocolon to lie posterolateral to sigmoid colon itself. **B.** A small knuckle of ileum has herniated into the intersigmoid fossa, leading to small bowel obstruction. (A from Martin LC, Merkle EM, Thompson WM: Review of internal hernias: Radiographic and clinical findings. *AJR Am J Roentgenol* 186:703-717, 2006. Reprinted with permission from the American Journal of Roentgenology.)

Retroanastomotic Hernia

Retroanastomotic hernias are a well-recognized and preventable complication of gastrointestinal surgery. They usually develop after partial gastrectomy and gastrojejunostomy. About 75% of cases involve incarceration of the efferent jejunal segment in the retroanastomotic space, which is created during antecolic or retrocolic anastomosis.^{2,4,26} The herniation is usually from right to left, so that the efferent jejunal loop or an excessively long afferent segment occupies the left upper quadrant of the abdomen. Less commonly, the ileum, the cecum, or the omentum is also involved.²⁷

Approximately half of these hernias occur in the first postoperative month, and the others occur within 1 year or several

Figure 112-7 Transmesenteric hernia. **A.** Coronal, reformatted CT scan shows a closed loop obstruction (circle) with clustering of small bowel loops and the small bowel feces sign. **B.** In a different patient, the obstructed loops converge at the mesenteric defect (arrow).

years after surgery.⁴ The presenting symptom is cramping abdominal pain, and the signs are those of high small bowel obstruction. The herniated loops are occasionally palpable as a tender mass in the left upper abdomen. These nonspecific findings may be mistaken for gastric outlet obstruction caused by stomal edema, dumping syndrome, or postoperative pancreatitis. Delay in establishing the correct diagnosis may lead to strangulation of the herniated loops; the associated mortality rate is up to 30% for surgically treated cases and almost 100% if the problem is not corrected.^{2,4,26}

Radiologic diagnosis of a retroanastomotic hernia requires careful fluoroscopic evaluation of the gastrointestinal tract after administration of barium or water-soluble contrast medium. The examination reveals that the site of obstruction is not the gastric stoma but is more distal in either of the anastomotic limbs. Gradual opacification of the partially obstructed efferent loop discloses its abnormal position lateral and posterior to the gastrojejunostomy (Fig. 112-9). The herniated segments of jejunum appear clumped or fixed in the left upper abdomen, usually associated with some degree of dilation and stasis.^{2,4,27}

The diagnosis of afferent loop hernia, which occurs primarily after an antecolic anastomosis, is more difficult. The clinical findings include persistent epigastric pain and tenderness, non-bilious vomiting, and elevated serum amylase level. Contrast studies of the upper gastrointestinal tract show patency of the anastomosis and the efferent loop; however, opacification of the herniated afferent limb may not occur or may be delayed. CT scans or sonograms of the upper abdomen usually disclose the obstructed afferent loop as a fluid-filled and markedly distended tubular structure.^{28,29} Scintigraphy is another diagnostic method for this entity. Radionuclide agents excreted by the biliary tract into the duodenum permit visualization of the dilated afferent loop and the site of obstruction.³⁰

Like any other symptomatic internal hernia, hernias involving the retroanastomotic space also require surgical correction. However, this iatrogenic hernia should be prevented during initial gastric operation by the use of a short afferent loop and the closure of the retroanastomotic space with sutures placed between the jejunal mesentery and the transverse mesocolon.^{2,4,26,27}

Figure 112-9 Retroanastomotic hernia. The diagram shows a retrocolic Roux-en-Y gastric bypass procedure. The arrow indicates a loop of small bowel protruding posterior to the enteroenterostomy, in keeping with a retroanastomotic internal hernia. (From Martin LC, Merkle EM, Thompson WM: *Review of internal hernias: Radiographic and clinical findings*. *AJR Am J Roentgenol* 186:703-717, 2006. ABDOMINAL WALL HERNIAS

Herniations through the walls of the abdominal cavity develop in approximately 1.5% of the population and usually involve specific sites of congenital weakness or previous surgical incision.¹⁻³ An outpouching of the peritoneum forms a hernia sac, which surrounds the protruding parts of the greater omentum, intestine, or other abdominal organs. The presenting symptoms are variable and depend on the size, location, and content of the hernia.

Umbilical Hernia

In infants and children, a patent umbilical ring is a common site of herniation. It often is manifested as a soft, asymptomatic bulge that tends to disappear spontaneously. In some instances, however, the development of umbilical tenderness and obstructive symptoms caused by incarceration necessitate surgical repair. The congenital entity known as an omphalocele is not a true umbilical hernia because the bowel loops never return to the peritoneal cavity during gestation in this disorder.

In adults, umbilical hernias occur predominantly in women with a history of multiple pregnancies and in patients with obesity or with increased abdominal pressure resulting from ascites and chronic bowel distention (Fig. 112-10). The hernia contents are usually the greater omentum and various segments of the small or large intestine. Adhesions often develop between the protruding viscera and the peritoneal sac and cause digestive symptoms and other complications.^{7,8}

The clinical diagnosis of an incarcerated umbilical hernia should be suspected when a patient presents with intestinal obstruction and umbilical tenderness, even if there is no obvious bulge on the surface. Radiographs of the abdomen usually show the distended bowel loops and a tumor-like density, the umbilical hernia. A coned-down lateral or cross-table view of the anterior abdominal wall using low peak kilovoltage can be

Figure 112-10 Types and locations of hernias. Herniations through the walls of the abdominal cavity usually involve specific sites of congenital weakness or previous surgical incision.

helpful in detecting the presence of omental fat or bowel loops in the umbilical hernia. Barium studies of the small or large intestine can show obstruction or protrusion of gut in the umbilical region. Ultrasound and CT studies of the abdomen establish the diagnosis when they demonstrate a “knuckle” of bowel protruding through an umbilical defect.³¹⁻³³

Ventral Hernia

The term *ventral hernia* encompasses several types of herniations through the anterior and lateral aspects of the abdominal wall (Fig. 112-11). Most occur in the midline and emerge through the aponeurosis forming the linea alba. They are referred to as epigastric or hypogastric hernias, depending on their location above or below the umbilicus, respectively. The hernia aperture is often a small, firm defect that allows portions of the greater omentum, properitoneal fat, or a bowel loop to protrude anteriorly.^{1,5-7,33} Incarceration and strangulation of the contents may occur frequently and produce symptoms out of proportion to the objective findings. The severity of abdominal pain may simulate a perforating peptic ulcer. The pain of a ventral hernia, however, is aggravated by exertion and associated with focal tenderness of the abdominal wall.

Lateral ventral hernias often occur spontaneously, but they frequently involve a site of previous abdominal surgery, laparoscopy, peritoneal dialysis, or stab wound. They are discussed later in conjunction with other incisional hernias. As a general rule, the radiologic features of various ventral hernias are similar to those of umbilical hernias. Barium studies demonstrate distended bowel loops proximal to a narrowing or obstruction in close relationship to a locally tender part of the abdominal wall. CT, magnetic resonance imaging (MRI), or sonography can reveal the defect and associated herniation in the ventral wall of the abdomen.^{5-7,31-34}

Figure 112-11 Ventral hernia. **A.** The longitudinal sonogram shows a ventral herniation of omental fat (arrows). **B.** Sagittal, reformatted image in a different patient shows herniated small bowel and mesentery (arrows).

Spigelian Hernia

Spigelian hernias are uncommon. They occur in the anterolateral aspect of the lower abdomen, along the semilunar line formed by fibrous union of the rectus sheath with the aponeuroses of the transversus abdominis and oblique abdominal muscles. The underlying cause is a congenital weakness in the posterior layer of transversalis fascia, through which the viscera prolapse between the lateral abdominal wall muscles as an interparietal or interstitial herniation.^{1,35-37}

Spigelian hernias are notoriously difficult to diagnose clinically because of their deep anatomic location and insidious development. Patients usually present with a prolonged history of intermittent lower abdominal pain and intestinal obstruction associated with a slight swelling or a vanishing anterolateral mass located midway between the umbilicus and the symphysis pubis. These hernias occur with almost equal frequency in males and females; they can be bilateral and associated with other ventral or inguinal hernias.

The usual contents of a spigelian hernia include the omentum and short segments of the small or large intestine. Barium enema or small bowel examination can be useful in establishing the diagnosis.³⁶ However, CT is the best imaging technique for visualizing the hernia defect involving the lateral border of the rectus sheath as well as interstitial protrusion of the omentum or intestinal loops (Fig. 112-12).^{5-7,37-39} Sonographic diagnosis can be made when there is a complex mass in the anterolateral wall of the lower abdomen, showing an echogenic component resulting from omental herniation or acoustic shadowing by the air-containing loops of incarcerated bowel.³⁷

Lumbar Hernia

Two areas of relative weakness in the flank can be sites of herniation. The superior lumbar space of Grynfeltt-Lesshaft is an inverted triangle bound by the 12th rib superiorly, the internal oblique muscle anteriorly, and the erector spinae muscle posteriorly.^{1,40,41} The inferior lumbar triangle (i.e., Petit's triangle) is bordered inferiorly by the iliac crest, anteriorly by the external oblique muscle, and posteriorly by the latissimus dorsi muscle.^{42,43}

Approximately 300 cases of lumbar hernia have been reported in the literature, and most involve the larger superior lumbar space. The contents usually include a bowel loop,

Figure 112-12 Spigelian hernia. CT shows herniated small bowel through a peritoneal defect at the lateral border of the left rectus muscle (arrow), which was a prior laparoscopic port site.

retroperitoneal fat, kidney, or, less frequently, other viscera. These hernias tend to enlarge gradually and cause symptoms ranging from chronic low back pain to intestinal obstruction. Bowel incarceration occurs in approximately 25% of these hernias and may lead to strangulation in about 10% of cases. The spontaneous and the post-traumatic types of lumbar hernias occur more frequently on the left side and in middle-aged men. The clinical manifestation as a soft, bulging mass in the flank may be mistaken for a lipoma or hematoma. Plain radiographs of the abdomen are often noncontributory, but barium studies can be useful when the bowel loops are contained within the hernia (Fig. 112-13). Certain articles indicate that CT can best delineate the precise location and content of lumbar hernias.^{5-7,40-43}

Figure 112-13 Lumbar hernia. CT shows the descending colon and mesentery herniating (arrow) posterolaterally through the left inferior lumbar space or Petit's triangle.

Incisional Hernia

Incisional hernias develop in approximately 5% of patients and represent a significant iatrogenic problem, given the fact that almost 3 million abdominal operations are performed annually in the United States. These hernias tend to occur during the first 4 months after surgery, a critical period for the healing of transected muscular and fascial layers of the abdominal wall. Their progressive enlargement is usually manifested within the first postoperative year, but 5% to 10% remain clinically silent for several years before they are detected.^{1,3,5}

The most common sites of involvement are along midline and paramedian incisions, although any surgical scar carries the potential risk of this complication. The clinical symptoms and physical findings of an incisional hernia depend on the size and rigidity of the underlying defect and on the extent of visceral protrusion. The properitoneal fat or the edge of the greater omentum is often the initial contents of a small incisional hernia, producing vague abdominal discomfort and localized tenderness of the healed scar. At a more advanced stage, a persistent bulging mass resulting from incarcerated bowel loops may be seen.

Approximately 10% of incisional hernias cannot be detected on physical examination. In obese patients, for example, the abundant subcutaneous fat can prevent palpation of a deeply seated peritoneal defect and the protruding viscera. The clinical diagnosis may also be difficult in patients with severe abdominal pain and distention or in the presence of a keloid or thick panniculus. The herniated segments occasionally dissect and are hidden between the muscular and the fascial layers of the abdominal wall. These interparietal or interstitial hernias often are manifested as localized swelling and tenderness adjacent to the surgical scar, but their actual content and internal orifice are seldom palpable. Under these circumstances, radiologic studies play a crucial role in establishing the correct diagnosis.^{3,5,34,44-47}

In patients with nonspecific abdominal pain and intermittent obstructive symptoms, a careful fluoroscopic evaluation of the gastrointestinal tract with barium may reveal a clinically occult or unsuspected incisional hernia. It is crucial that areas

Figure 112-14 Incisional hernia. The CT scan performed 1 year after laparotomy shows a knuckle of transverse colon (arrow) protruding beneath a healed midline incision.

with old surgical scars be viewed in profile while the patient strains. This maneuver assists in detection of reducible hernias that may otherwise be overlooked.⁴⁶ CT can best show small defects in peritoneal and fascial layers of abdominal wall through which the omentum or a knuckle of intestine protrudes into the subcutaneous fat.^{3,31-34} It can also disclose ischemic changes caused by strangulated bowel loops, a sign of a surgical emergency (Fig. 112-14). Sonographic detection of an incisional hernia is also possible by visualization of a bowel loop causing acoustic shadowing within the disrupted abdominal wall layers beneath a healed scar.

Most incisional hernias are ventral, but other potential sites should be considered in patients who previously had abdominal surgery. For example, an acquired lumbar hernia may be present in the area of flank incision for nephrectomy.⁴¹ A parastomal herniation of the omentum or intestine may also occur where the distal bowel loop has tunneled through the abdominal wall (Fig. 112-15). In a similar manner, postcholecystectomy patients can develop intermittent bowel herniation beneath the right subcostal incision. These hernias may not be appreciated during physical examination but are easily detectable on barium studies or abdominal CT.^{3,5,7,44}

PELVIC AND GROIN HERNIAS

Almost 75% of all abdominal hernias occur in the groin and account for more than a half-million operations per year in the United States.^{1,34} Most are inguinal hernias that are easy to diagnose by inspection and palpation. Radiologic studies are performed primarily for preoperative delineation of the herniated viscera and associated complications or when the clinical findings are equivocal because of the deep location of a pelvic wall herniation.

Inguinal Hernia

In its most common type, known as indirect inguinal hernia, the peritoneal sac containing bowel loops protrudes through the inguinal canal and emerges at its external ring. This hernia occurs predominantly in males and can extend along the

Figure 112-15 Peristomal hernia. **A.** Axial CT image demonstrates portions of the ascending colon (large arrow) along the posterolateral aspect of the patient's colostomy (small arrow) in a peristomal hernia. **B.** Coronal, reformatted CT image shows portions of the hepatic flexure of the colon (arrow) in the hernia.

spermatic cord into the scrotum (Fig. 112-16). In females, the hernia follows the course of the round ligament of the uterus into the labium majus.^{1,34}

The development of indirect inguinal hernia has a congenital basis. During embryologic migration of the testis, a peritoneal sac called the processus vaginalis accompanies testicular descent into the scrotum; in females, it follows the round ligament. In both sexes, this peritoneal communication is normally obliterated before birth; however, about one third of infants and 15% of adults have a patent processus vaginalis on one or both sides. This allows the subsequent development of an inguinal hernia when abdominal viscera are pushed into the open sac.^{34,37}

The contents of indirect inguinal hernias usually include small bowel loops or mobile colon segments such as the sigmoid colon, cecum, and appendix. The other viscera and pelvic adnexa are less frequently involved. The term *sliding inguinal hernia* is used when partially retroperitoneal organs, such as the urinary bladder, distal ureters, or ascending or descending colon, are included in the herniation. Their preoperative demonstration is important because retroperitoneal structures constitute the wall of the hernia sac and may be injured during its surgical repair. The blood vessels supplying the herniated segments of ascending or descending colon course in the posterior wall of sliding hernias and are subject to inadvertent trauma if an incorrect surgical approach is used.

Indirect inguinal hernias account for 15% of intestinal obstructions; only neoplasms (32%) and adhesions (18%) are more common causes.⁸ The symptoms of an incarcerated or strangulated hernia include bowel distention associated with painful and often tense swelling in a groin or the scrotum. Radiographs of the abdomen obtained with the patient supine can indicate the correct diagnosis by showing the convergence of distended intestinal loops toward the inguinal region and a soft tissue density or gas-containing mass overlying the obturator foramen on the affected side. Barium examination of the small or large bowel typically shows a tapered narrowing or obstruction of the intestinal segment as it enters the hernia orifice. Every attempt should be made to reduce the hernia

manually under fluoroscopy and to clearly visualize the afferent and efferent loops of protruding intestine. It is important to recognize that diverticulitis, appendicitis, and primary or metastatic tumors may occur within the hernia sac.⁴⁷⁻⁵⁰ CT and ultrasound examinations of the groin can also provide useful diagnostic information on the hernia contents and on its differentiation from other masses involving the groin or scrotum (see Fig. 112-16).^{32,34}

The *direct inguinal hernia* is a less common type of groin hernia that occurs mostly in men and seldom in women or children. It represents visceral protrusion directly through the lower abdominal wall in a weak area medial to the inferior epigastric vessels. This hernia appears as a small bulge in the groin. It rarely becomes incarcerated because of its short and blunt aperture.^{1,34} It can be differentiated from indirect hernias, which have an elongated, oblique course through the inguinal canal and frequently extend into the scrotum.

Simultaneous occurrence of direct and indirect inguinal hernias in the same groin is unusual. In these cases, the separation of the two adjacent hernia sacs by the inferior epigastric vessels creates a bilocular appearance. This entity is therefore referred to as a saddlebag, a pantaloons, or *combined inguinal hernia*.^{1,34,51}

Two other varieties of abdominal herniations occur:

1. In *Littre's hernia*, a Meckel diverticulum protrudes into the hernia sac. This usually occurs in the right inguinal region but may also be associated with other ventral or pelvic hernias.^{1,52}
2. *Richter's hernia* contains only a part of the bowel wall circumference as a localized outpouching (Fig. 112-17). The intestinal lumen remains patent, and no obstructive symptoms are produced despite intense pain and tenderness caused by incarceration of the bulging bowel wall into a postoperative or postlaparoscopic defect.^{3,53-55}

Femoral Hernia

Herniation into the femoral canal occurs predominantly in women and accounts for about one third of groin hernias in

Figure 112-16 Inguinal hernia. **A.** Coronal, reformatted CT image shows a nonobstructing, right inguinal hernia containing small bowel (arrow). **B.** An axial image shows the herniated segment of ileum (arrow). **C.** Coronal, reformatted CT image reveals an obstructing, right inguinal hernia containing a small segment of ileum (arrow). **D.** Sagittal sonogram in a different patient demonstrates an inguinal hernia containing fat, fluid, and gut (arrow). **E.** Barium enema examination demonstrates herniation of the distal ileum into the right scrotum (small arrow). There is herniation of the sigmoid colon into a left inguinal hernia (large arrow).

women. The incidence in men is three to four times lower, and children are rarely affected.^{56,57} The hernia contents are usually properitoneal fat, edge of the omentum, or loop of small bowel (Fig. 112-18). They can displace or narrow the femoral vein and descend along the saphenous vein. However, the neck of a femoral hernia always remains below the inguinal ligament and lateral to the pubic tubercle.

Femoral hernias are often difficult to diagnose clinically because of the deep location of the femoral canal and the abundance of overlying adipose tissue. Nevertheless, they are 8 to 12 times more prone to incarceration and strangulation than are inguinal hernias because of the firm and unyielding margins of the femoral ring. The correct radiologic diagnosis can therefore be important.^{7,58-60}

Obturator Hernia

The site of this uncommon herniation is the obturator canal (Fig. 112-19) in the superolateral aspect of the obturator foramen. It is an obliquely oriented, fibro-osseous tunnel measuring about 2 to 3 cm long and 1 cm in diameter, through which the obturator nerve and vessels course.

Approximately 80% to 90% of obturator hernias occur in elderly women, probably because of enlargement of the obturator canal after pregnancies and aging. They are more common on the right and usually contain an ileal loop, but other viscera or pelvic adnexa may also be involved.^{1,34,60} The protruding structures are often incarcerated in the canal or in the space between the pectineus and the obturator muscles. Most patients

Figure 112-17 Incarcerated Richter's hernia. **A.** Double-contrast colon examination shows a funnel-shaped traction deformity involving the inferior border of the sigmoid loop (arrows). **B.** CT of the lower pelvis reveals a small left inguinal hernia containing the air-filled outpouching of sigmoid wall (arrow). **C.** Another section 2 cm caudad shows a fatty mass within the hernia sac (arrow), representing an incarcerated epiploic appendage that pulled the adjacent sigmoid wall.

Figure 112-18 Femoral hernia. An obstructing right femoral hernia (large arrows) is identified on the coronal (**A**), axial (**B**), and sagittal (**C**) CT images. Notice the relationship to the inguinal canal (**B**, thin arrow).

present with acute or recurrent bowel obstruction and a tender mass in the obturator region detected on rectal or vaginal examination. About half the patients experience pain radiating along the medial aspect of the thigh when the leg is extended or abducted (i.e., Howship-Romberg sign) because of obturator nerve compression by the hernia.

The radiologic diagnosis of obturator hernia should be considered whenever abdominal radiographs or barium studies show bowel obstruction together with a fixed loop containing some gas or contrast medium in the obturator region. CT of the pelvis is most valuable in revealing the hernia as a soft tissue mass or opacified loop that protrudes through the obturator foramen and extends between the pectineus and the obturator muscles.⁶¹⁻⁶³

Sciatic Hernia

The greater sciatic notch is bordered by the lateral margin of the sacrum and the inferior border of iliac bone. The sacrotuberous ligament converts this semicircular structure into the greater sciatic foramen. This opening is the pathway for the sciatic nerve, the gluteal vessels and nerves, and the piriformis muscle. It also represents a potential site of herniation of the pelvic or abdominal viscera into the subgluteal region.^{5,64-66} The lesser sciatic foramen, a small slit located farther caudally, is less prone to this complication.

About 50 cases of sciatic hernia have been reported, with most involving the distal ureter or a loop of the small bowel.^{64,66} Clinical manifestations are usually lower abdominal cramps, urinary symptoms, pain radiating to the dorsal aspect of the thigh or leg, and a palpable, tender mass in the gluteal region. Plain radiographs of the abdomen are seldom helpful, but excretory urography can disclose the characteristic curlicue appearance of herniated distal ureter. Barium studies of the small bowel or colon and CT scans may be used to show a bowel loop that has herniated through the sciatic foramen and extends laterally into the subgluteal region (Fig. 112-20).

Perineal Hernia

Herniations involving the pelvic floor are uncommon and occur mainly through the urogenital diaphragm. Defects in the levator ani or coccygeus muscle can lead to more posterior perineal hernias.^{60,67}

Most patients with perineal hernias are women older than 50 years. Causal factors include acquired weakness of the pelvic

Figure 112-20 Sciatic hernia. A small knuckle of ileum (arrow) is identified behind the right acetabulum. There is no associated obstruction.

Figure 112-21 Diaphragmatic hernias. Cross-sectional drawing depicts the common locations of Morgagni, Bochdalek, and hiatal hernias. Several elements are indicated: juxtacaval fat (arrow), foramen of Bochdalek (green), esophageal hiatus (pink), and foramen of Morgagni (yellow). floor caused by increased abdominal pressure from pregnancy, obesity, or ascites; local inflammatory processes; and postsurgical defects after abdominoperineal resection or transperineal prostatectomy. Clinical findings usually consist of a perineal or gluteal mass, which may cause discomfort when sitting. Barium enema or small bowel examination can be used to demonstrate the protruding loop adjacent to the anus or in one of the buttocks.^{60,67} CT scans can also depict the hernia sac and its contents in the ischiorectal fossa.⁶⁸

DIAPHRAGMATIC HERNIAS

Diaphragmatic hernias (Fig. 112-21) are classified as four types: esophageal hiatus, Morgagni, Bochdalek, and traumatic. Esophageal hiatal hernias are discussed in Chapter 28.

Foramen of Morgagni Hernia

Foramen of Morgagni hernias usually contain the omentum and transverse colon (Fig. 112-22) and occasionally contain the stomach and small bowel, surrounded by their peritoneal sac. They protrude through the retrosternal foramen of Morgagni, which is wider than normal because of a natural weakness of the sternocostal muscle bundles. About 90% of cases occur on the right side. In adults, these hernias are usually asymptomatic.⁶⁸⁻⁷¹

Foramen of Bochdalek Hernia

Foramen of Bochdalek hernias occur through the lumbocostal trigone of Bochdalek. In these cases, there is defective closure of the pleuropulmonary hiatus (Fig. 112-23). In neonates, these hernias are conspicuous in size and often need surgical repair. In adults, these hernias are small and usually result from hypoplasia of the lumbocostal muscle bundles surrounding Bochdalek's foramen. They are usually found incidentally in

asymptomatic patients. MDCT is useful in determining the extent of the diaphragmatic defect and the contents of the hernia sac. This canal is a communication between the thoracic cavity and the retroperitoneal space. These hernias are more common on the left than on the right.⁶⁸⁻⁷¹

Traumatic Hernias

Diaphragmatic disruption can develop from blunt trauma (e.g., auto accidents, falls, crush injuries, bout of hyperemesis) or penetrating trauma (e.g., bullet and knife wounds, repair of hiatal hernia). Rupture occurs in 0.8% to 1.6% of all blunt trauma and represents 5% of all diaphragmatic hernias but 90% of all strangulated diaphragmatic hernias.⁶⁸⁻⁷¹

The left hemidiaphragm is injured three times more commonly than the right in traumatic diaphragmatic hernias. Organ herniation occurs in 32% to 58% of cases and most often involves, in descending order, the stomach, colon, small bowel, omentum, spleen, kidney, and pancreas.⁶⁸⁻⁷¹ The most frequent injuries associated with diaphragm rupture in auto accidents include laceration of the liver and spleen, rib and pelvic fractures, and pulmonary contusion. Bergqvist's triad includes rib fractures, spine or pelvic fractures, and diaphragmatic rupture.

The reported accuracy of CT in the detection of these hernias is variable, with a sensitivity ranging between 61% and 100% and specificity between 77% and 100%.⁶⁸⁻⁷¹ Coronal and sagittal reformatting of the volumetric MDCT data may be helpful in establishing the diagnosis but is not always definitive and can be misleading.

Several signs are helpful in identifying traumatic rupture: diaphragm discontinuity, segmental nonrecognition of diaphragm, intrathoracic herniation of abdominal contents, collar sign, elevated abdominal organs, thickened diaphragm, thoracic fluid abutting intra-abdominal organs, dependent viscera sign, hemothorax and hemoperitoneum, and extravasation of contrast material at level of diaphragm. The dependent viscera sign (Fig. 112-24) is contact of the upper third of the liver on the right or the stomach or bowel on the left with the posterior ribs. The collar or hourglass sign is focal constriction of the stomach or liver at the site of herniation through the diaphragm. Abrupt discontinuity of the diaphragm may be visible with or without herniation of viscera. The absent diaphragm sign is lack of visualization of the diaphragm in an area where it does not

Figure 112-22 Foramen of Morgagni hernia. CT scan shows a retrosternal hernia that includes the omentum and colon (arrow). Notice the fanlike disposition of the mesenteric vessels (dashed arrow).

Figure 112-23 Foramen of Bochdalek hernias. **A.** Small bowel (arrow) is seen herniated in this right foramen of Bochdalek hernia. **B.** The left kidney and perinephric fat are contained in this left foramen of Bochdalek hernia (arrow).

Figure 112-24 Traumatic diaphragmatic hernias: the dependent viscera sign. **A.** In a 32-year-old man with left-sided diaphragmatic rupture, an axial CT scan shows discontinuity of left hemidiaphragm (arrows indicate extent of diaphragmatic tear) with gastric and left renal herniation. The stomach lies dependent on left posterior ribs, which is a positive dependent viscera sign. **B.** In a 32-year-old woman with ruptured right hemidiaphragm, an axial CT scan shows the right lobe of the liver dependent on right posterior ribs (black arrows), which is the dependent viscera sign. A partial, waistlike constriction (white arrow)—the collar sign—is visible along anterior surface of right lobe of liver and is attributable to partial hepatic intrathoracic herniation. (**A** and **B** from Bergin D, Ennis R, Keogh C, et al: *The “dependent viscera” sign in CT diagnosis of blunt traumatic diaphragmatic rupture*. *AJR Am J Roentgenol* 177:1137-1140, 2001. Reprinted with permission from the American Journal of Roentgenology.)

contact and is normally seen. Active extravasation of contrast material at the level of the diaphragm and asymmetric thickening of the diaphragm also suggest injury. Elevation of the hemidiaphragm alone is not specific to diaphragmatic rupture because it can be the result of eventration, phrenic nerve injury, or preexisting paralysis.⁶⁸⁻⁷¹

This diagnosis is often difficult, and traumatic hernias often go undetected for days or even years because of subtle changes on chest radiographs, nonsurgical management of thoracic or abdominal injuries, and diversion of attention to more immediate life-threatening injuries. Other diagnostic difficulties arise because left-sided defects may be covered by omentum; right-sided defects may be sealed by the liver; positive pressure ventilation may prevent herniation of abdominal contents into the thorax until mechanical ventilation is discontinued; and atelectasis, pleural effusion, lung contusion, or phrenic nerve paralysis may mask the tear. Onset of symptoms may be so long delayed that the traumatic event is forgotten.⁶⁸⁻⁷¹

Anterior Abdominal Wall

The muscles and fascial layers of the anterior abdominal wall provide containment, support, and protection for the intraperitoneal contents and are involved in movement and breathing. These structures usually receive little attention in cross-sectional imaging, but they can be involved in a wide variety of congenital, inflammatory, neoplastic, and iatrogenic processes. In CT and MRI, routine imaging protocols are usually adequate to evaluate abdominal wall lesions; ultrasound examinations must be tailored to the evaluation of the anterior abdominal wall through the use of high-frequency (5-7.5 MHz) transducers with short focus. All of these techniques provide excellent anatomic detail for the evaluation of anterior abdominal wall disease.

ANATOMY

The anatomy of the anterior abdominal wall can be discussed in two regions. The anterior wall of the abdomen and upper

pelvis is a relatively simple, multilayered structure, whereas the fascial planes, spaces, and structures of the lower pelvis are more complex. These anatomic relationships dictate the origin and spread of disease processes.

In general, superficial to deep dissection of the anterior abdominal wall exposes skin, subcutaneous fat, superficial muscle fascia, one or more muscles, deep muscle fascia, properitoneal fat, and the peritoneum.^{72,73} The rectus muscle is present on either side of the midline linea alba, which runs from the xiphoid process to the symphysis pubis (Fig. 112-25). Along its superior aspect, the rectus abdominis muscle is surrounded by the aponeurosis of the three flank muscles. Approximately halfway between the umbilicus and the symphysis pubis, the aponeurosis of the internal oblique muscle and the transversus abdominis muscle no longer contribute to the posterior aspect of the rectus sheath. This transition, marked by the arcuate line, leaves the rectus invested posteriorly only by the thin transversalis fascia from the arcuate line to the pubic symphysis. The lateral abdominal muscles (from superficial to deep) include the external oblique, internal oblique, and transversus abdominis muscles, and they are separated from the rectus by the linea semilunaris. Asymmetry of abdominal wall muscles is common and often results from congenital variation or postoperative atrophy. The properitoneal fat stripe is frequently evident on plain radiographs. Ascites causes a shift of this lucency away from the adjacent colon, whereas inflammatory lesions of the peritoneal cavity or abdominal wall can obliterate it.

An anatomic model analogous to the retroperitoneal spaces around the kidneys has been advanced to simplify the understanding of the extraperitoneal spaces surrounding the bladder.⁷⁴ The umbilicovesical fascia originates at the umbilicus and spreads as a fan-shaped structure around the urachus, obliterated umbilical arteries, and bladder to terminate in the fascial layers of the deep pelvis. In this way, the umbilicovesical fascia is analogous to Gerota's fascia, creating a prevesical space anterior to the umbilicovesical fascia (like the anterior pararenal space) with a perivesical space between this fascia and the bladder (like the perirenal space). The analogy to the perirenal spaces is completed by noticing that the bladder, urachus, and

Figure 112-25 Anterior abdominal wall anatomy. **A.** Axial CT image of the normal anatomy of the abdominal wall: external oblique muscle (white arrow), internal oblique muscle (red arrow), transversus abdominis muscle (yellow arrow), linea semilunaris muscle (blue arrow), and rectus abdominis muscle (black arrow). **B.** Coronal CT image of the normal anatomy of the abdominal wall: aponeurosis (white arrow) and linea alba (red arrow).

obliterated umbilical arteries lie in the perivesical space, parallel to the kidneys, ureters, and adrenal glands in the perirenal space. The prevesical space represents a large potential space. Fluid collections in this space can be confined to the low pelvis, where this compartment is also known as the retropubic space or the space of Retzius. Larger collections, however, quickly track upward and laterally into the properitoneal space. Fluid in the prevesical space can also enter the rectus sheath below the level of the arcuate line, probably at perforations in the transversalis fascia of the inferior epigastric vessels. The perivesical space, however, is confined closely around the bladder.⁷⁴

CONGENITAL LESIONS

Urachal Abnormalities

The urachus is an extraperitoneal tubular structure that courses from the umbilicus to the bladder dome. It is the obliterated remnant of the allantois and perhaps of a portion of the cloaca. This three-layered cord is lined with transitional epithelium supported by a layer of blood vessels and lymphatics enclosed by a muscle layer.⁷⁵ Dissections of fetuses have shown that at or before birth, the urachus has involuted into a fibrous cord or is patent as a 1-mm tube extending from the bladder dome. This lumen is usually quickly obliterated.⁷⁶

Four congenital lesions of the urachus are known: patent urachus, urachal cyst, urachal sinus, and vesicourachal diverticulum.^{75,77} Patent urachus is evident in the first moments or days of life. The umbilical cord may be thickened and tense

from urine reflux, and an umbilical hernia may be present. Urine leaks from the umbilicus when it is ligated. Numerous series have reported an association between patent urachus and lower urinary tract obstruction (14%-50% of cases), but it is not clear whether urethral obstruction is the direct cause of patent urachus.⁷⁵ The diagnosis is confirmed by analyzing the expressed fluid for urea and creatinine, by observing a color change at the umbilicus when dye is injected into the bladder, or with fistulography performed by cannulating the opening at the umbilicus.⁷⁵ Voiding cystourethrography may demonstrate the communication, and it offers the additional benefit of excluding a lower obstruction.

If only a portion of the urachus remains unobliterated, a urachal cyst occurs. It frequently becomes apparent in adults as an enlarging mass, a sensation of fullness, or infection. These lesions require cross-sectional imaging for detection because there is no communication with the bladder or umbilicus.⁷⁸ CT or ultrasound offers the immediate advantage of cyst puncture and drainage for diagnostic purposes. A course of percutaneous drainage and antibiotic therapy is beneficial preoperatively to reduce infectious complications at surgery.⁷⁹ Untreated infected cysts usually drain to the anterior abdominal wall, but they may spontaneously rupture into the peritoneal cavity.⁷⁵ Definitive therapy requires complete excision with resection of a cuff of bladder dome.^{80,81}

A urachal sinus is likely the result of an infected urachal cyst that dissects and drains to the umbilicus or, less commonly, to the bladder. These lesions are manifested with umbilical

drainage or urinary tract infection. Other communicating tracts may exist if a remnant of the omphalomesenteric duct allows a connection to the bowel lumen, mesentery, or peritoneal space. Fistulography is useful for delineating the course of the tracts, and complete excision is required.

Omphalomesenteric Duct Abnormalities

Rarely, anomalies of the omphalomesenteric duct are manifested as periumbilical processes.^{75,77} This tubular structure connects the umbilicus to the gut in early embryonic development and is usually obliterated by the 10th week of gestation. A variety of malformations can arise if part or all of this communication from the gut to the umbilicus remains open.⁷⁷ Incomplete closure of the deep end of this structure leads to the development of Meckel's diverticulum, which is the most common omphalomesenteric abnormality. Rarely, a patent duct allows free communication from the ileum to the umbilicus. This lesion can be easily differentiated from patent urachus by noticing the nature of the discharge and by performing fistulography. If only the superficial end of the duct is patent, an omphalomesenteric sinus is present, which is manifested with mucoid discharge. A polypoid mass of small bowel mucosa may be present.⁸² If both ends of the duct close but the midportion is not obliterated, an omphalomesenteric (vitelline) cyst forms and mucoid secretions from the intestinal lining accumulate.⁷⁵

Prune-Belly Syndrome

Prune-belly syndrome, also known as Eagle-Barrett syndrome, is a constellation of absence of the anterior abdominal wall muscles, cryptorchidism, and dilation of ureters and bladder; it has no known cause.^{83,84} The manifestations vary; the most profoundly affected infants die at or shortly after birth of pulmonary hypoplasia resulting from oligohydramnios (i.e., Potter's syndrome). Milder cases are treated by repair of undescended testes or vesicoureteral reflux. Milder cases may have only slight wrinkling of the anterior abdominal wall or diastasis of the rectus musculature.⁸³ CT easily demonstrates the defects in the anterior abdominal wall and the genitourinary abnormalities.

FLUID COLLECTIONS

Hematoma

Hematomas of the anterior abdominal wall frequently involve the rectus sheath, although lateral collections do occur (Fig. 112-26).⁷³ These hematomas originate from tears in muscle fibers or blood vessels and may be spontaneous or related to trauma, surgery, anticoagulation, straining, coughing, or iatrogenic causes such as needle biopsy or aspiration.^{85,86} Pain, blood loss, ecchymosis, and abdominal mass may suggest the correct diagnosis, but clinical signs are often absent or nonspecific. Pain or fever may suggest the presence of abscess or other acute intra-abdominal process, and an accurate diagnosis is required to avoid unnecessary intervention.⁸⁶

Rectus sheath hematomas above the arcuate line are simple to diagnose because of their location and configuration. Transverse images demonstrate ovoid expansion of the rectus sheath. Longitudinal images show a spindle-shaped lesion.⁸⁶ Below the arcuate line, these collections extend into the prevesical space to displace and to compress the pelvic viscera.⁸⁷ Other diagnoses, such as urinoma, abscess, or lymphocele, must be considered for pelvic fluid collections. Conversely, urinomas, abscesses, or lymphoceles starting in the prevesical space can mimic a

Figure 112-26 Lateral abdominal wall hematoma. A hematocrit effect (white arrow) is identified. Notice that active extravasation of contrast material (red arrow) is present.

rectus sheath hematoma if they track cranially. The subfascial hematoma from cesarean section is also a prevesical hematoma, located between the uterus and the anterior abdominal wall. Because the surgical approach is different, this lesion must be differentiated from a bladder flap hematoma, which arises between the lower uterine segment and the bladder.⁸⁸

Arterial puncture in the femoral sheath with subsequent hematoma formation has the potential to involve the anterior abdominal wall. The femoral sheath is contiguous superiorly with the transversalis fascia, and hematomas formed in the femoral sheath can expand rapidly to fill the prevesical space. These hematomas can extend into the rectus muscles or lateral abdominal wall muscles.¹⁸ Blood can also track directly from the groin into the lateral abdominal wall, primarily along the transversalis fascia and transversus abdominis muscle.^{89,90} In any case of retroperitoneal, extraperitoneal, or abdominal wall hematoma, clinical signs and symptoms are poorly localized and underrepresent the hematoma. CT is useful for documenting the full extent of the lesion, and changes over time are readily apparent. Continued bleeding requires surgical intervention.⁹¹

The CT, ultrasound, and MRI appearances of blood vary with the age of the clot, the hematocrit of the patient, and, in the case of CT or MRI, the use of contrast material, which alters the appearance of surrounding muscle.⁸⁵ On CT scans, blood is commonly hyperdense and heterogeneous. The hyperdensity is within areas of clot and is surrounded by lower attenuation collections of serum. Dependent layering of cellular elements in a hematoma can be demonstrated by CT or ultrasound (see Fig. 112-26).⁸⁵ The MRI appearance of blood is highly variable and can frequently be indistinguishable from tumor or abscess.⁹²

Urinoma

Bladder rupture usually occurs in the setting of blunt abdominal trauma, often with pelvic fracture. Penetrating and iatrogenic injuries to the bladder are occasionally encountered. The distended urinary bladder can rupture into the intraperitoneal space because of tears along the dome of the bladder.

Extraperitoneal bladder rupture can be confined solely to the perivesical space or can extend into the prevesical space of Retzius or into the scrotum, thigh, penis, or retroperitoneum.⁹³ Urinomas from bladder rupture are part of the differential diagnosis of anterior abdominal wall fluid collections. CT can frequently demonstrate these collections, but cystography is superior for urethral injury and remains required whenever bladder rupture or urethral injury is suspected.^{93,94}

Abscess and Cellulitis

Focal inflammatory lesions of the anterior abdominal wall can be postoperative, post-traumatic, or spontaneous (i.e., associated with diabetes mellitus or immunosuppression). They can also represent extension of an intra-abdominal process, such as abscess or Crohn's disease.^{73,95,96} Often, these lesions occur in postoperative or critically ill patients, with concomitant sepsis. Like hematomas, abdominal wall abscesses are difficult to fully delineate by clinical means. CT, MRI, and ultrasound have been advocated as methods for evaluation of abdominal wall infections.^{73,95,96} The goals of any cross-sectional examination for this indication are fourfold. First, the inflammatory lesion must be carefully localized. Whereas a subcutaneous abscess may respond to simple incision and drainage, deeper lesions may require more aggressive therapy. Second, evidence for underlying causative factors, such as Crohn's disease, infected or perforated tumor, or intra-abdominal abscess, should be sought. In this regard, ultrasound has a significant limitation because of the difficulty of recognizing bowel or mesenteric lesions.⁹⁶ Third, cellulitis or phlegmon without a well-defined fluid collection must be differentiated from frank abscess because antibiotic therapy alone is inadequate to cure an abscess. Fourth, percutaneous drainage should be offered in appropriately selected cases. CT remains the imaging procedure of choice for inflammatory lesions of the abdominal wall because it accurately delineates intraperitoneal and retroperitoneal associated processes and offers appropriate planning information and guidance for drainage.⁹⁵

Smaller abdominal wall abscesses are usually ovoid or spindle shaped. As they enlarge, they become progressively more mass-like. They may displace structures such as liver, spleen, or bladder and can be mistaken for intraperitoneal or retroperitoneal collections.⁹⁵ CT or ultrasound usually resolves the fluid components necessary to differentiate abscess from cellulitis (Fig. 112-27). In general, cellulitis and phlegmon have ill-defined margins, with the exception of any margin sharply defined by a fascial plane.⁹⁵

Necrotizing fasciitis is a rare form of aggressive soft tissue infection usually seen in diabetics or alcoholics. This entity is usually caused by an underlying infection of the lower genitourinary tract or soft tissues of the perianal region, and most infections are centered in the pelvis,⁹⁷ although necrotizing fasciitis has also been reported in other locations. It can arise spontaneously or from blunt or penetrating trauma, surgery, venous stasis, or decubitus ulcers.⁹⁸ Thrombosis of small subcutaneous arteries is seen on pathologic examination, and the resultant ischemia likely allows the aggressive infection to occur.⁹⁷ Soft tissue gas has been emphasized as the radiologic hallmark of this disorder,⁹⁸ but gas alone is not sufficient for the diagnosis to be made because soft tissue gas may result from fistulas, drains, penetrating injury, or molecular oxygen from hydrogen peroxide wound irrigation.⁹⁹ Most patients with necrotizing fasciitis are toxic at the time

Figure 112-27 Abdominal wall abscess. An abscess (arrow) involves the rectus abdominis muscles in this postoperative patient. Notice the inflammatory changes in the subcutaneous fat.

of presentation and require aggressive antibiotic therapy and surgical débridement. Mortality rates of 20% to 50% have been reported.⁹⁸ Another unusual form of abdominal wall infection is actinomycosis. This infection usually involves the abdominal wall by direct inoculation at trauma, extension from an infected intra-abdominal source, or blood-borne infection. Although these lesions are responsive to penicillin, they mimic neoplasm. The correct diagnosis is often not made until surgical biopsy.¹⁰⁰

NEOPLASMS

Primary Malignant Neoplasms

Primary malignant neoplasms of the anterior abdominal wall are uncommon. They include sarcomas, desmoid tumors (i.e., tumors of mesenchymal origin), and urachal carcinoma. Sarcomas are further subtyped histologically as rhabdomyosarcomas, fibrosarcomas, leiomyosarcomas, liposarcomas, synovial sarcomas, malignant schwannomas, malignant fibrous histiocytomas, and poorly differentiated sarcomas.^{101,102} Desmoid tumors represent a low-grade, nonmetastasizing variant of fibrosarcoma, and they have a unique tendency to arise in musculoaponeurotic planes. They are locally aggressive tumors and may involve bowel loops or bladder deep to the tumor or adjacent ribs or pelvic bones.^{101,102} Their histologic appearance, local invasiveness, and predilection for recurrence have inspired their other name of *aggressive fibromatosis*. Desmoid tumors most often occur in women of childbearing age and sometimes arise in a preexisting surgical scar.¹⁰¹⁻¹⁰³ Desmoid tumors arise frequently in the colectomy scar of patients with Gardner's syndrome and may be accompanied by desmoid tumors of the mesentery or paraspinous musculature.¹⁰⁴

Differentiation of desmoid tumors from the various sarcomas is often not possible unless distant metastatic disease is present.⁷³ Desmoids are frequently well defined.¹⁰⁵ Fibrous tumors are often hypoechoic sonographically and hyperdense compared with muscle on CT studies, particularly on postcontrast scans.¹⁰⁵⁻¹⁰⁷ MR scans show the expected low signal intensity of fibrous tissue on T1- and T2-weighted images, and the multiple imaging planes available with MR scanning may have

Figure 112-28 Abdominal wall metastatic malignant neoplasm. **A.** Longitudinal sonogram demonstrates a hypoechoic metastasis (cursors) within the subcutaneous fat of the anterior abdominal wall from a gastric carcinoma. **B.** Enhancing abdominal wall metastasis (arrow) from colon cancer.

some advantage in showing the origin and extent of these lesions.³⁷ These lesions require wide excision, and preoperative evaluation of the extent of the lesion is invaluable for surgical planning.¹⁰⁷

Urachal carcinoma is a rare lesion, usually arising in the juxtavesical segment of the urachus. Classic clinical features include the passage of blood or mucus in the urine. These lesions are most commonly adenocarcinoma (94%), and they usually occur in males (75%).¹⁰⁸ The lesion is frequently calcified; it deforms the bladder apex and may shift the ureters laterally.¹⁰⁸

Metastatic Disease

Although subcutaneous metastatic deposits are usually clinically evident, they may be overlooked, particularly in the obese patient. These soft tissue lesions are usually well visualized because of the naturally homogeneous background provided by subcutaneous fat. CT, ultrasound, or MRI can demonstrate these lesions, and changes in these metastases over time can be used as one marker of response to chemotherapy (Fig. 112-28).¹⁰⁹ Typical primary lesions that cause subcutaneous metastases include melanoma and lung, renal, and ovarian cancer.⁷³ Direct spread of a variety of intra-abdominal malignant neoplasms to the abdominal wall is also common. A unique, iatrogenic form of spread to the abdominal wall is occasionally seen in patients with indwelling drains placed to manage malignant obstruction of the biliary tract.¹¹⁰ Rarely, percutaneous biopsy can seed subcutaneous metastasis.¹¹¹ Gastric cancer has a peculiar predilection to produce an isolated metastasis near the umbilicus. This probably represents a form of peritoneal metastasis rather than nodal spread.¹¹²

Benign Lesions

A variety of benign tumors of the abdominal wall can be manifested as soft tissue masses. These lesions, discovered incidentally, include lipomas, neurofibromas, and other mesenchymal tumors.⁷³ On occasion, endometriomas can occur in the anterior abdominal wall, incorporated in a surgical scar, typically in the setting of prior cesarean section. These hormonally responsive lesions can be painful at the time of menses and can be easily missed with pelvic ultrasound if the near field is not carefully examined.¹¹³

MISCELLANEOUS CONDITIONS

Vascular Lesions

Small, subcutaneous blood vessels are frequently evident on abdominal CT scans; however, an increase in the size or number of these vessels (usually veins) should raise suspicion of an intra-abdominal venous abnormality. Veins are recognized by their intense enhancement and tubular or serpiginous configuration on multiple, contiguous images. Abdominal wall venous collateral vessels may occur in the setting of systemic venous occlusion or portal hypertension, and the appearance of the collateral vessels alone often does not lead to a definitive diagnosis. Patients with portal hypertension usually have a large number of associated findings that lead to the correct diagnosis, including retroperitoneal, mesenteric, perisplenic, or paraesophageal varices and cirrhotic hepatic changes.¹¹³⁻¹¹⁵ One specific collateral vessel, the recanalized umbilical or paraumbilical vein, is highly specific for portal hypertension.¹¹³⁻¹¹⁵ This vessel drains the portal venous system from the left portal vein along the falciform ligament into the anterior abdominal wall, terminating in many paraumbilical systemic veins, causing caput medusae.

Vascular Grafts

Surgically placed arterial grafts are easily identified in the subcutaneous tissues by CT, ultrasound, or MRI.⁷³ Axillary-femoral bypass grafts are oriented parallel to the long axis of the body along the lateral abdominal wall, whereas femoral-femoral grafts cross the lower abdomen just above the symphysis pubis. Patency of these grafts is usually apparent by palpation but can be confirmed by Doppler ultrasound.⁷³

Other Implanted Devices

Chronic ambulatory peritoneal dialysis is performed on patients in renal failure by sequentially infusing fluid into the peritoneal cavity and removing it to allow removal of toxins and regulation of electrolytes. This technique requires the placement of a catheter that crosses the anterior abdominal wall. Leaks, hernias, or fluid collections at the catheter entry site are optimally demonstrated by CT (Fig. 112-29). It is beneficial to infuse dialysate mixed with an iodinated contrast agent to enhance visualization of the configuration of the peritoneal lining at the catheter site.¹¹⁵

Figure 112-29 CSFoma: CT features. There is a fluid collection (arrow) in the subcutaneous fat of the anterior pelvic wall due to malposition of ventriculoperitoneal shunt tube (red arrow).

Other devices, such as infusion ports, chemotherapy reservoirs, and cardiac pacemakers, are commonly seen with cross-sectional imaging. Unless the device was placed recently, the presence of gas or fluid around the implant should raise suspicion of infection.

Calcifications

Hypercalcemic states, dermatomyositis, idiopathic calcinosis, Ehlers-Danlos syndrome, injection granulomas, and epidermolysis bullosa can cause subcutaneous calcification.¹¹⁵ These can be precisely located by CT.

Subcutaneous Gas

Although most cases of subcutaneous gas are caused by trauma or surgery, infection and ruptured viscus must also be considered.⁷³ These collections are well localized on CT scans, and underlying pathologic conditions, including fistulas to bowel and abscesses, also can be evaluated.¹¹⁵⁻¹¹⁷

Figure 112-30 Trocar deformity. Anterior abdominal wall trocar-associated hernias (red arrow) are seen causing small bowel obstruction (yellow arrow) with the small bowel feces sign.

Laparoscopic Injuries

Laparoscopic surgery is being used for an increasing number of indications in the abdomen and pelvis. This surgery requires at least four holes in the abdominal wall created by a trocar. Each one of these holes can lead to the formation of a permanent defect (Fig. 112-30), which can serve as a pathway for future herniation.¹¹⁸⁻¹²⁰

Conclusions

Cross-sectional imaging provides an excellent, noninvasive means of evaluating pathologic processes of the anterior abdominal wall. Specific observations on the nature, location, extent, and underlying causes of these lesions can be made, therapy planned and instituted, and follow-up accomplished.

Pediatric Disease

Applied Embryology of the Gastrointestinal Tract

BRUCE R. JAVORS | ROI M. BITTANE

CHAPTER OUTLINE

Early Development

Division of the Intraembryonic Celom and Formation of the Diaphragm

Anomalies of Diaphragmatic Development

Diaphragmatic Hernia
Foramen of Morgagni Hernia
Eventration

Normal Liver Development

Abnormal Liver Development

Atypical Segmentation
Atypical Location

Normal Gallbladder and Bile Duct Development

Abnormal Gallbladder and Bile Duct Development

Phrygian Cap
Gallbladder Diverticulum
Positional Anomalies
Bifid Gallbladder or Duplication
Agenesis
Tracheobiliary Fistula
Biliary Atresia
Alagille's Syndrome
Cystic Disease
Caroli's Disease
Choledochal Cysts

Normal Development of the Esophagus

Abnormal Development of the Esophagus

Tracheoesophageal Fistula
Duplication
Stenosis
Esophageal Bronchus
Congenital Short Esophagus

Normal Development of the Stomach, Duodenum, and Lesser Omentum

Abnormal Development of the Stomach and Duodenum

Antral Web
Gastric Diverticula
Duplications
Duodenal Stenosis
Duodenal Web and Inverted Diverticulum

Normal Development of the Pancreas

Abnormal Development of the Pancreas

Annular Pancreas
Pancreas Divisum
Ectopic Pancreatic Tissue

Normal Development of the Lesser Sac and Greater Omentum

Abnormal Development of the Lesser Sac and Greater Omentum

Infracardiac Bursa
Omental Cyst

Normal Development of the Spleen

Abnormal Development of the Spleen

Accessory Spleen
Wandering Spleen
Asplenia
Polysplenia
Splenic-Gonadal Fusion

Normal Midgut Rotation and Fixation

Abnormal Midgut Rotation and Fixation

Duplication
Ileal Atresia
Mesenteric Cyst
Nonrotation
Reversed Rotation
Incomplete Rotation and Malrotation
Hyperrotation
Internal Herniations
Meckel's Diverticulum

The complex anatomy of the gastrointestinal tract and the peritoneal cavity arises from much simpler origins. The transition from the primitive straight tubular alimentary canal to the elongated and tortuous gut (and its accessory organs) suspended by mesenteries and encased by peritoneal reflections can readily be explained by a well-defined series of events. Although these processes are summarized individually, these multiple events often occur simultaneously with complex interactions.

Early Development

After fertilization, the zygote rapidly undergoes repeated mitotic divisions that result in an increased number of cells. This occurs without a corresponding increase in the cell mass.

Approximately 3 days after fertilization, a solid ball of cells (i.e., morula) develops. The next day, central cavities appear, which separate the cells into the trophoblast (from which part

of the placenta develops) and the embryoblast. Two days later, endometrial implantation begins.

During the second week of development, the spherical mass of cells flattens into a bilaminar disk. A primitive yolk sac also develops. During the third week, the embryonic disk rapidly develops into the embryo (i.e., gastrulation). The cells differentiate into the three classic germ cell layers: endoderm, mesoderm, and ectoderm.

The endoderm gives rise to the lining epithelium of the respiratory and gastrointestinal tracts as well as the glandular elements of the liver and pancreas. From the mesoderm arise the smooth muscle of the gastrointestinal tract, the connective tissues, and their associated blood vessels. Blood cells and their progenitors, striated muscle, bone, cartilage, and the reproductive and genitourinary tract are also mesodermal in origin. The ectoderm is the source of the epidermis and the nervous system.

Clefts appear within the lateral aspects of the developing intermediate mesodermal layer, forming the intraembryonic celom. These open laterally into the yolk sac. They lie between and separate the more dorsal somatic mesoderm from the ventral splanchnic mesoderm.¹ The somatic mesoderm, in association with the ectodermal layer, forms the embryonic body wall (i.e., somatopleure); the splanchnic mesoderm, along with the endoderm, forms the embryonic gut (i.e., splanchnopleure) (Fig. 113-1).

As the lateral margins of the embryonic disk move ventrally and medially, they begin to pinch off the yolk sac and the more laterally placed intraembryonic celom. Continued growth by the somatopleure and its eventual midline fusion complete the encompassment of the intraembryonic celom with formation of a cylindrical body cavity. The more centrally placed splanchnopleure also starts to close ventrally, partially separating the primary yolk sac into the gut and the secondary yolk sac, which is separated by the yolk stalk (Fig. 113-2).

A primitive alimentary tube is formed within the larger surrounding body cavity. The dorsal mesentery and its visceral peritoneum are derived from the splanchnopleure. Most of the ventral mesentery, also derived from the splanchnopleure, degenerates with time, leaving a large embryonic body cavity (i.e., celom).²

Figure 113-1 Embryologic development: early fourth week.

Cross section through the midportion of an embryo early in the fourth week shows infolding of the somatopleure as it begins to encase the intraembryonic celom. This eventually encompasses the body cavity. The splanchnopleure's contribution to the formation of the midgut is evident.

Division of the Intraembryonic Celom and Formation of the Diaphragm

During the fourth to sixth weeks of development, the large common intraembryonic celomic cavity is partitioned into pleural, pericardial, and peritoneal spaces. By the fourth week, a large pericardial cavity is connected to the peritoneal cavity by two smaller pericardioperitoneal canals. The pressure of the developing head causes the heart and pericardial cavity to be displaced caudally and ventrally. The pericardioperitoneal canals exit from the pericardium along its dorsal aspect to enter the peritoneum.

As the lung buds develop, they grow into the paired pericardioperitoneal canals. This produces two pairs of ridges. The cranial pair gives rise to the pleuropericardial membrane that eventually separates the primitive pericardial cavity into definitive pericardial and pleural spaces. The more caudal pair gives rise to the pleuroperitoneal membrane. This plays an important role in the development of the diaphragm. As the lung buds grow superiorly and the liver and peritoneal space expand inferiorly, these membranes become more prominent. They attach themselves to the abdominal wall along their dorsal and lateral margins. Their free edges project into the pericardioperitoneal canals.

During the sixth week, the free edges of the dorsolateral pleuroperitoneal membrane fuse with the midline dorsal mesentery of the esophagus, forming part of the primitive mediastinum at this point. The anterior half of the primitive diaphragm is formed by the septum transversum, which arises in the third week as a condensation of mesoderm. By the fourth week, it has thickened to form an incomplete division anteriorly between the pericardium and the peritoneal cavity (Fig. 113-3).

Between weeks 6 and 12, many changes take place in the relative contributions of these structures to the diaphragm that exists at birth. The large dorsolateral component formed by the pleuroperitoneal membranes decreases in size. Myoblasts from the abdominal wall migrate into the peripheral aspects of the membranes. These contribute to the growth of the diaphragm

Figure 113-2 Embryologic development: late fourth week.

The cross section is similar to that in Figure 113-1, but it shows development at the end of the fourth week. The envelopment of the intraembryonic celom is almost complete. The yolk sac has separated into a more definitive yolk stalk and midgut.

Figure 113-3 Embryologic development: fifth week. Diagram of a 5-week embryo as seen from below. The relative contributions of the septum transversum, esophageal mesentery, and pleuroperitoneal membranes change with further development.

and eventually give rise to the costophrenic sulci. Myoblasts also grow into the primitive dorsal esophageal mesentery, forming the diaphragmatic crura.

In addition to its complex formation, the diaphragm markedly shifts in position. In the fourth week, the septum transversum is at the level of the third to fifth cervical somites. The myoblasts and associated nerve innervation also arise from these levels. From the fourth to the sixth weeks, the dorsal part of the embryo grows rapidly, causing an apparent descent of the diaphragm. The mesenchyme of the septum transversum contributes its own myoblasts to the diaphragm, maintaining its original C3-C5 innervation. In its definitive state, the diaphragm lies at the level of the thoracolumbar junction while maintaining its phrenic nerve, midcervical innervation.

Anomalies of Diaphragmatic Development

DIAPHRAGMATIC HERNIA

If the pleuroperitoneal membrane fails to close entirely, a patent canal may persist between the pleural and the peritoneal cavities. If this dorsally and laterally placed canal is still present at the reduction of the physiologic herniation of the midgut at week 10 (discussed later), the returning bowel may herniate through this patent foramen of Bochdalek into the chest. This occurs most frequently on the left side.²

FORAMEN OF MORGAGNI HERNIA

A natural weakness in the anteromedial portion of the diaphragm (i.e., retrosternal) is caused by the passage of the superior epigastric vessels. Herniation of omentum or intestines may occur at this site, and it occurs most frequently on the right side.³

EVENTRATION

Defective muscle development of the dome of the diaphragm may lead to structural weakness and subsequent ballooning. Only a thin, aponeurotic sheet of tissue is then present. Abdominal contents may bulge into the thoracic cavity, simulating a difficult to differentiate eventration from a true herniation.

Normal Liver Development

During the fourth week of development, the caudal portion of the foregut develops a ventral bud called the primordial hepatic diverticulum. This endodermal liver bud enlarges and grows into and between the two layers of the ventral mesentery. More superiorly, it grows in contact with and into the mass of mesenchyme, the septum transversum. The ventral liver bud divides into cranial and caudal portions within the mesentery. The cranial portion gives rise to the liver and intrahepatic bile ducts; the caudal portion forms the gallbladder and cystic duct.⁴

The cranial liver bud further divides into right and left lobes, which are initially of equal size. The right lobe eventually becomes much larger than the left. The distal branches of the right and left lobe cords undergo canalization to become the definitive main right and left hepatic ducts. The intrahepatic biliary tree is thought to arise from the hepatic parenchyma. These cords of tissue extend along the randomly created pattern of portal vein tributaries (discussed later). Consequently, the pattern of intrahepatic bile ducts is variable.

The mature liver has two ligaments that represent remnants of embryologic vascular channels. These are the ligamentum teres (i.e., round ligament) within the falciform ligament and the ligamentum venosum. These develop from the vitelline and umbilical veins, respectively. The paired vitelline veins drain the yolk sac, pass through the developing liver and septum transversum, and empty into the right side of the primitive heart (i.e., sinus venosus). The vitelline veins within the liver create a meshlike network of vascular channels that become the hepatic sinusoids. Some of the lining cells of the sinusoids later differentiate into macrophages (i.e., Kupffer cells), the reticuloendothelial component of the liver.⁵ The segments of the vitelline veins proximal and distal to the sinusoids become, respectively, the hepatic veins and the hepatic portion of the portal vein.⁶

The paired umbilical veins drain the placenta and chorion. They pass through the septum transversum, contributing minimally to hepatic sinusoidal development, and then empty into the sinus venosus. The entire right umbilical vein and a segment of the left proximal (cephalad) to the liver atrophy. A large venous channel, the ductus venosus, arises from the hepatic sinusoidal network and carries blood from the distal (caudal) left umbilical vein into the sinus venosus, bypassing the liver. Eventually, the lumen of the ductus venosus is obliterated, and the structure becomes the ligamentum venosum. The distal portion of the left umbilical vein migrates medially to the liver edge, and its lumen closes. It then becomes the round ligament (i.e., ligamentum teres). This ligament, which connects the ligamentum venosum to the umbilicus, is encased within the most anterior portion of the ventral mesentery, the falciform ligament (Fig. 113-4).⁷

The mesenchymal septum transversum contributes to the ventral mesentery that surrounds the liver and gallbladder. The fibrous tissues of the liver, including Glisson's capsule,

Figure 113-4 Falciform ligament and bare area of liver. CT of the upper abdomen shows a large amount of ascites (A) outlining the falciform ligament (*straight arrows*). Along the posterior aspect of the right lobe, there is a region not surrounded by the fluid: the bare area (*curved arrows*). This represents the portion of the liver that developed in contact with the septum transversum and that is not covered by the peritoneum.

embryonal hepatic hematopoietic tissues, and the Kupffer cells lining the sinusoids, are also derived from the septum transversum.⁷

The membranous ventral mesentery is a double-layered structure that encloses the liver and gallbladder to become their visceral peritoneum. The cephalic portion of the developing liver directly contacts the septum and therefore is not enveloped by the ventral mesentery. This region, devoid of peritoneum, is known as the bare area (see Fig. 113-4). The visceral peritoneum reflects off the liver onto the undersurface of the diaphragm as the coronary ligaments outlining this region.

Abnormal Liver Development

ATYPICAL SEGMENTATION

Variations of lobulation sometimes occur. A bipartite liver results from an exaggerated separation of the lobes, which may represent congenital absence of the medial segment of the left lobe.⁸

Absence of the right lobe may result from maldevelopment of the portal vein or the primordial hepatic diverticulum proper.^{9,10} A portal venous abnormality may account for an absent left lobe. Multilobar livers—as many as 16—may be seen.⁷ Hepatic anomalies are discussed further in Chapter 85.

ATYPICAL LOCATION

Hepatic lobes can develop in the thorax. They may undergo torsion when they have a separate mesentery.¹¹ Heterotopic liver tissue may also be found within structures that share a common embryologic development: gallbladder, pancreas, umbilical cord, and gastrohepatic ligament.¹²

Normal Gallbladder and Bile Duct Development

The fourth week of embryogenesis is marked by the appearance of the hepatic diverticulum. It then divides into cranial and caudal buds. The caudal bud forms the gallbladder, cystic duct, and extrahepatic bile ducts. Their development precedes that of the intrahepatic ducts by several weeks.

The common bile duct develops as a cord connecting the cystic and main hepatic ducts to the descending duodenum. The hollow gallbladder and common bile duct primordia become occluded with proliferating endoderm during the fifth week. They recanalize by vacuolization and cell degeneration by the end of that week. The recanalization of the common bile duct precedes that of the gallbladder and duodenum. As the duodenum rotates 90 degrees to the right, the common bile duct rotates an additional 180 degrees along with the ventral pancreatic anlage. The common duct is carried from its original ventral position to the right, then posteriorly, and finally to the medial aspect of the duodenal sweep.

The gallbladder and intrahepatic ducts also communicate through the cystohepatic ducts of Luschka during fetal life. These ducts usually atrophy in the adult but may remain patent in some patients. When they persist and are not recognized during cholecystectomy, a significant bile leak may result.¹³

Vacuoles in the wall of the duodenum coalesce to form two separate channels and then one single lumen for the adjacent common bile and main pancreatic ducts. Within the wall of the duodenum are primitive ampullary tissues that enlarge and displace the junction of the two ducts away from the duodenal lumen. This displacement is reversed by the growth of the duodenal wall smooth muscle. This accounts for the considerable variability seen in the junction of these two structures.^{14,15}

Abnormal Gallbladder and Bile Duct Development

PHRYGIAN CAP

The phrygian cap is an abnormal shape of the gallbladder. It represents a folding of the fundus on itself and is not truly pathologic.

GALLBLADDER DIVERTICULUM

The gallbladder diverticulum is the true diverticulum (containing all normal wall elements). It probably is the remnant of the cystohepatic duct. It can be a site of bile stasis and stone formation (see Chapter 76).¹⁶

POSITIONAL ANOMALIES

The most common anomaly of gallbladder position is that of a “wandering” or “floating” gallbladder. Elongation of the gallbladder mesenteric attachment to the undersurface of the liver results in excessive mobility. The gallbladder may herniate into the lesser sac, undergo torsion, or be located in other intra-abdominal locations (see Chapter 76).^{7,16-19}

BIFID GALLBLADDER OR DUPLICATION

A bifid gallbladder has two cavities but only one cystic duct. Each of the duplicate or triplicate gallbladders has its own cystic duct. These entities may result from a persistent outpouching of the extrahepatic duct or incomplete recanalization of the gallbladder.^{5,7,16,18} The latter may also give rise to a septate gallbladder (see Chapter 76).^{7,20}

AGENESIS

Agenesis, a rare entity, results from a lack of development of the caudal portion of the liver bud or improper recanalization of the gallbladder.^{6,7,18,21} It may be associated with a host of other anomalies affecting many other organ systems (see Chapter 76).

TRACHEOBILIARY FISTULA

Tracheobiliary fistula is characterized by the combination of bile-stained sputum and pneumobilia. It results when the biliary tree is connected to the carinal region.^{7,18,22}

BILIARY ATRESIA

In biliary atresia, the number of intrahepatic bile ducts is decreased. This may develop primarily or result from α_1 -antitrypsin deficiency, cystic fibrosis, or viral hepatitis (see Chapter 120).²³

ALAGILLE'S SYNDROME

Alagille's syndrome is an autosomal dominant syndrome of arteriohepatic dysplasia. It is characterized by a paucity of bile ducts, peripheral pulmonic stenosis, vertebral anomalies, and mental and physical retardation (see Chapter 119).²⁴

CYSTIC DISEASE

The spectrum of cystic diseases ranges from intrahepatic cysts or fibrosis to renal disease. Various patterns of inheritance also occur. Cysts may be attributable to defective development of the intrahepatic ducts. In other forms, bile duct hyperplasia and portal fibrosis may predominate (see Chapters 76 and 119).

CAROLI'S DISEASE

Caroli's disease is a nonfamilial entity characterized by segmental cystic dilation of the intrahepatic bile ducts. It may represent an intermediate form of disease between congenital hepatic fibrosis and choledochal cysts.¹⁸ A possible cause is perinatal hepatic artery occlusion.²⁵ Multiple episodes of cholangitis may result from bile stasis (see Chapter 76).

CHOLEDOCHAL CYSTS

Multiple theories have been proposed to explain choledochal cysts.²⁶⁻²⁸ These concepts include distal biliary ductal obstruction with subsequent weakening and ballooning of the wall, anomalous course of the bile duct through the duodenal wall, and deficient development of the bile duct wall. Additional theories include a high junction of the bile and pancreatic ducts proximal to the sphincter of Oddi, which

allows reflux of pancreatic enzymes up the common bile duct when the sphincter is contracted, resulting in cholangitis and dilation. Another theory suggests an excess quantity of epithelial cells in the primitive choledochus, followed by recanalization leading to cyst formation. Viral infection leading to infantile obstructive cholangiopathy is another widely favored theory. During the past decade, technologic advances in imaging have greatly enhanced the noninvasive evaluation of the biliary tract. For example, multidetector computed tomography (CT) and magnetic resonance cholangiopancreatography (MRCP) can accurately depict preoperative anatomy and enable delineation of an anomalous pancreaticobiliary junction.²⁹

Choledochal cysts are found more often in Asians and in females. Five classic radiographic types have been identified.³⁰ The most common type is aneurysmal dilation of the common duct, which often extends into the cystic duct and the main hepatic ducts. The rare second form is a diverticulum that projects off the distal common duct. The third form is that of a choledochoceles, which represents a dilation of the distal common bile duct that protrudes into the duodenum. This third form may also be a congenital duplication cyst of the duodenum through which the common duct courses (see Chapter 76).³¹

Two other types are included in the classification of choledochal cysts. One is multifocal segmental intrahepatic and extrahepatic ductal dilation. The other is Caroli's disease (discussed earlier).

Normal Development of the Esophagus

During the latter half of the fourth week, the respiratory system develops as a ventral bud of the foregut. The laryngotracheal groove forms at the caudal end of the primitive pharynx and becomes the laryngotracheal diverticulum. Longitudinal (tracheoesophageal) folds eventually separate the ventral respiratory apparatus from the dorsal esophagus.

Initially, the esophagus is relatively short. Growth of the heart and lungs contributes to the elongation of the esophagus. Its epithelium and epithelial glands proliferate and obliterate the hollow lumen. This cellular plug is resorbed by the eighth week, the end of the fetal period.

Abnormal Development of the Esophagus

TRACHEOESOPHAGEAL FISTULA

Partial fusion of the tracheoesophageal folds leads to incomplete separation of the respiratory and gastrointestinal tracts (i.e., tracheoesophageal fistula). This is usually accompanied by some narrowing of the associated lumens (i.e., esophageal atresia). This common anomaly is discussed further in Chapter 114.

DUPLICATION

Incomplete resorption of the endothelial plug may result in a duplication of the esophagus (see Chapter 114).³² Duplication cysts are manifested as submucosal masses and do not usually

communicate with the esophageal lumen. CT or endoscopic sonography can document its cystic nature.

STENOSIS

Weblike narrowing or long segmental strictures may occur in the distal esophagus. Stenosis results from incomplete recanalization (see Chapter 114).³³

ESOPHAGEAL BRONCHUS

An esophageal bronchus is evidence of the common origin of the respiratory and gastrointestinal tracts. In this entity, a branching bronchus arises from the esophagus, usually in association with a pulmonary sequestration.³⁴

CONGENITAL SHORT ESOPHAGUS

If the esophagus does not proportionally elongate as the body grows, a congenital short esophagus occurs.³³ Seen at birth in association with a hiatal hernia, it is distinct from the acquired form found in adults.

Normal Development of the Stomach, Duodenum, and Lesser Omentum

At the end of the fourth week, which is the midpoint of the fetal period, the primitive stomach is still a straight, hollow tube in the midsagittal plane. During the next 2 weeks, the future stomach dilates, first in a fusiform manner and then with preferential growth of its dorsal wall. This causes a dorsal bulge, which is the origin of the greater curvature.

During the sixth to eighth weeks of development, the stomach rotates along two different axes simultaneously. The first and major rotation about the longitudinal axis causes the dorsal bulge to form the lateral border of the stomach. The former ventral aspect forms the medial wall (i.e., lesser curvature).³³ This accounts for the left vagus nerve innervating the anterior wall of the stomach and the right vagus nerve innervating the posterior wall in the adult (Fig. 113-5).

The enlarging liver contributes to a second rotation about the anteroposterior axis. The stomach shifts from a

purely longitudinal orientation to one more transverse. The greater curvature convexity is directed inferiorly and laterally, whereas the lesser curvature is concave superiorly and medially.

The ventral mesentery of the distal foregut persists into adulthood. It continues to connect the lesser curvature of the stomach (i.e., former ventral wall) to the undersurface of the liver at the junction of the caudate lobe and the lateral segment of the left lobe as the gastrohepatic ligament (Fig. 113-6).³⁵ Within it lie the left gastric artery, coronary veins, and multiple lymph nodes. The more caudal portion of the lesser omentum forms the hepatoduodenal ligament. Within its free edge lie the hepatic artery, portal vein, common hepatic and bile ducts, and lymph nodes.³⁶ This free edge forms one of the borders of the foramen of Winslow, separating the lesser sac from the greater peritoneal cavity.

Unlike the dorsal bulge of the primitive stomach, the duodenum forms a ventral bulge. The proximal portion of the duodenum (i.e., from the pylorus to just past the papilla) is derived from the foregut, maintaining its blood supply from the celiac axis (i.e., major foregut artery). The remainder of the duodenum is derived from the midgut. Consequently, it is supplied by the superior mesenteric artery (i.e., major artery of the midgut), which passes through the persistent dorsal mesentery.

With gastric rotation, the duodenum also changes in position. The concave border formerly directed dorsally becomes open to the left (i.e., classic C loop). The dorsal mesentery is subsequently resorbed, leaving a covering of visceral peritoneum along its anterior surface. This loss of mesenteric attachment accounts for the final “retroperitoneal” location of the duodenum distal to the bulb.

Abnormal Development of the Stomach and Duodenum

ANTRAL WEB

An antral web is a thin, concentric narrowing of the antrum. It is composed of mucosa and submucosa (Fig. 113-7). It may be congenital in origin (i.e., a recanalization error) or may be associated with peptic ulcer disease.³⁷

GASTRIC DIVERTICULA

Gastric diverticula usually occur high on the posterior wall of the fundus, and they may be true diverticula or pseudodiverticula with an absent muscle wall.³⁷ The constancy of position suggests an underlying congenital basis.

DUPLICATIONS

Duplications usually are found along the greater curvature. These noncommunicating cystic masses vary greatly in size (see Chapter 116).^{37,38}

DUODENAL STENOSIS

Duodenal stenosis is manifested as a narrowing of variable length, usually in the third and fourth portions. It may result from faulty recanalization (see Chapter 116).³³

Figure 113-5 Gastric rotation and formation of the lesser sac. **A** and **B**. Schematic cross-sectional diagrams depict the rotation of the stomach about the body's longitudinal axis. The left vagus nerve is carried to the anterior wall of the stomach. The extension of the right peritoneal space posterior to the stomach starts the formation of the lesser sac.

Figure 113-6 Embryologic origins of mesenteries and supporting ligaments. Cross section through a 5-week embryo at the level of the liver shows the paired superior peritoneum (right and left) separated by the ventral and dorsal mesenteries. Even at this stage of development, the origins of many of the suspensory ligaments of the adult are clearly demonstrated.

Figure 113-7 Antral web. There is a thin, linear, nonobstructive defect (arrows) in the gastric antrum.

DUODENAL WEB AND INVERTED DIVERTICULUM

A thin, narrow band of tissue may partially block the duodenum. With the continued pressure of peristalsis propelling intestinal contents, this web may stretch and balloon into a saclike structure within the normal duodenal lumen, the so-called inverted diverticulum or windsock deformity (see Chapter 116).³⁹

Normal Development of the Pancreas

The endoderm of the caudal foregut produces dorsal and ventral pancreatic buds during the fourth week of development.

The dorsal bud appears first and lies cephalad to the ventral anlage. The dorsal bud rapidly grows into the dorsal mesentery (i.e., mesoduodenum). It gives rise to the body and tail of the pancreas. The more caudal ventral pancreatic bud develops from the hepatic diverticulum. This bud is originally bifid, but the left side atrophies, and the right side persists to form the uncinete process and the head of the pancreas.^{40,41}

The dorsal bud has been reported to have a greater propensity for fatty infiltration than the ventral bud, which may be useful in distinguishing normal pancreatic parenchyma from diseased pancreas between the pancreatic buds on imaging studies.⁴² This propensity may stem from the different histologic composition of the pancreatic buds. Microscopic evaluation indicates that the parenchyma originating from the ventral bud contains densely packed pancreatic lobules, whereas the parenchyma originating from the dorsal bud is relatively loosely packed and contains more interposed adipose tissue.⁴³

CT evaluation of focal fatty infiltration, most often observed in the anterior aspect of the pancreatic head, demonstrates an isolated region of fat attenuation within the pancreatic parenchyma on non-contrast-enhanced or contrast-enhanced studies. However, contrast-enhanced CT studies may mask the presence of focal fatty infiltration as the normal parenchyma enhances and obscures the low-attenuation regions of fat. It is noteworthy that the delineation between the region of fatty infiltration and the remaining pancreatic parenchyma is often smooth and sharp, as would be expected in infiltration resulting from differing histologic composition.^{43,44}

On ultrasound, focal fatty infiltration is hyperechoic compared with the normal pancreatic parenchyma. As on CT, there is a discrete delineation between the segment of the pancreas with fatty infiltration and the remaining parenchyma.⁴⁴

Magnetic resonance imaging is an accurate modality for evaluating focal fatty infiltration (and differentiating it from a neoplastic lesion) because of its ability to clearly identify fatty tissues. Fatty tissue will show high signal intensity on T1- and T2-weighted images. In addition, with use of chemical shift imaging, it can be shown that fatty infiltration tissue shows a significant signal decrease on the out-of-phase T1 sequence compared with the in-phase T1 sequence.^{43,44}

There are several important imaging clues that help differentiate a mass from focal fatty infiltration of pancreatic parenchyma. Focal fatty infiltration is more often found in the anterior aspect of the pancreatic head, whereas the posterior aspect of the pancreatic head and the parenchyma adjacent to the pancreatic duct are spared. Compared with a malignant lesion, for example, fatty infiltration does not usually exert mass effect on the surrounding tissues or vessels and often maintains the normal contour of the pancreas. Finally, focal fatty infiltration tends to be stable on repeated studies.

As the duodenum rotates 90 degrees to the right, the dorsal pancreatic bud and its mesentery are carried along in the concavity of the primitive duodenal sweep (discussed earlier). They are ultimately situated along the left (medial) margin of the descending duodenum. The common bile duct and the right side of the ventral pancreatic anlage also complete this 90-degree rotation while undergoing an additional 180-degree rotation of their own. They come to lie along the concavity of the duodenal sweep after rotating through a total of 270 degrees (Fig. 113-8A, B).

Eventually, the duodenal dorsal mesentery fuses with the posterior peritoneal wall, resulting in the retroperitoneal location of the pancreas. However, a small portion of the tail of the pancreas maintains its intraperitoneal location near the hilum of the spleen in a portion of the mesogastrium that sometimes is not fully resorbed.⁴⁰

During the sixth week, the parenchyma of the ventral and dorsal buds and their ducts unite. The main pancreatic duct (Wirsung), which empties through the main papilla, is derived from the ventral anlage in the head and the dorsal anlage in the body and tail (Fig. 113-8C). The accessory duct (Santorini) is derived from the distal aspect of the dorsal anlage, and in 10% of patients, it empties through the minor papilla.⁴⁰ In the remaining cases, the main pancreatic duct is the predominant excretory pathway as the two ductal systems communicate.

The exocrine pancreatic tissue is derived from the pancreatic buds, which produce tubules. Vesicles form at the ends of these tubules, which give rise to acini. The endocrine islets of

Langerhans also derive from the endoderm.⁴⁰ The splanchnic mesenchyme adjacent to the pancreas provides its connective tissue stroma.³³

Abnormal Development of the Pancreas

ANNULAR PANCREAS

In 85% of cases of this anomaly, the descending duodenum is surrounded by a band of pancreatic tissue.^{40,41} An annular pancreas is most often found in male patients, and it may be associated with other congenital anomalies in up to 75% of cases (see Chapter 96).

According to one theory, the left bud of the originally bifid ventral pancreas persists and helps contribute to the ring of tissue around the duodenum.⁴⁵ Another theory proposes that the tip of the right bud abnormally adheres to the duodenum as it and the anlage rotate, thereby stretching and wrapping the pancreatic tissue around the duodenum.^{40,41}

PANCREAS DIVISUM

Pancreas divisum is caused by failure of the dorsal and ventral pancreatic buds to unite. This allows the uncinate process and a portion of the head to be drained by a short and narrow-caliber main pancreatic duct (Wirsung) through the major papilla. The remainder is drained by the accessory pancreatic duct (Santorini) through the minor papilla that lies cephalad and ventral to the major papilla. The narrow opening of the minor papilla may predispose these patients to pancreatitis (see Chapter 96).⁴⁶ Advances in MRCP have proved accurate in the diagnosis of pancreatic divisum. Multidetector CT using cine visualization or multiplanar reformatting may also improve the visualization of ductal anatomy in patients with pancreatic divisum.^{47,48} Endoscopic ultrasound with a linear array transducer can demonstrate atypical ductal anatomy. The cleavage plane between the ventral and dorsal

Figure 113-8 Stages of pancreatic development: superior perspective. **A.** Starting in the fourth week, the ventral pancreatic anlage rotates 180 degrees (first to the right and then posteriorly) as the duodenum rotates 90 degrees. This results in a total rotation of 270 degrees, with the original ventral anlage moving to the left of the duodenum. This rotation also carries the distal common bile duct posterior to the duodenum. **B.** The dorsal anlage is carried along by the duodenal rotation, such that it lies to the left of the duodenum. **C.** By the seventh to eighth week, the ducts of the two pancreatic buds fuse with the ventral pancreas, contributing the distal portion of the main pancreatic duct. Most of the proximal main duct arises from the dorsal anlage.

pancreatic anlagen may also be demonstrated by this technique.⁴⁹

ECTOPIC PANCREATIC TISSUE

Small islands of pancreatic tissue may grow along the greater curvature of the antrum or medial aspect of the duodenal sweep, with formation of submucosal nodules.^{37,39} Other sites of involvement, including the omentum, have also been reported (see Chapter 96). Fully developed ducts are rare.

Normal Development of the Lesser Sac and Greater Omentum

With the resorption of the ventral mesentery along the midgut and its persistence along the distal foregut, the abdomen is divided into paired (left and right) cephalic peritoneal spaces and a larger, common space caudally. As the primitive stomach develops, the dorsal mesentery (i.e., mesogastrium) with its accompanying vascular supply starts to elongate markedly. The elongated mesogastrium is carried along with the dorsal bulge of the stomach as it rotates (described earlier). This causes the right half of the paired cephalic peritoneal space to extend posterior to the stomach into the left upper quadrant, forming the lesser sac (see Fig. 113-5).

The most dorsal aspect of this elongated mesogastrium (containing the spleen) eventually fuses partially with the posterior abdominal wall, accounting for the retroperitoneal course of the splenic artery (Fig. 113-9).³⁶ The more ventral portion of the now redundant mesogastrium projects anteriorly and inferiorly. It hangs from the greater curvature of the stomach and overlies the transverse colon and mesenteric small bowel. It then loops back on itself to rejoin its already fused dorsal component at the posterior abdominal wall (Fig. 113-10A).

The two leaves of this redundant apron of mesentery fuse, obliterating the space between the two layers (i.e., inferior recess of the lesser sac). The greater omentum, composed of four layers of peritoneum, hangs like an apron over much of the peritoneal cavity. The greater omentum partially fuses with

the transverse colon and its suspending dorsal mesentery (Fig. 113-10B).^{33,36} Ventrally, this gives rise to the gastrocolic ligament as the greater omentum adheres to the superior aspect of the transverse colon. Dorsally, the mesogastrium and mesocolon fuse to form the definitive transverse mesocolon.^{33,36} This delineates the inferior border of the lesser sac. The transverse mesocolon takes rise over the pancreas and may act as a pathway for the spread of disease from the retroperitoneal pancreas to the intraperitoneal colon.⁵⁰ The retroperitoneum fascia is composed of multiple discrete layers that represent fused leaves of the apposed embryonic mesentery. These planes, which extend from the diaphragm to the pelvic floor, enable rapid accumulations of fluid to spread in the retroperitoneum (see Chapter 108).⁵¹

The foramen of Winslow is the entry point into the lesser sac. It is bordered by the free edge of the hepatoduodenal

Figure 113-9 Rotation of the mesogastrium. Schematic cross-sectional diagram through the upper abdomen reveals continued rotation of the elongated mesogastrium containing the splenic bud. This rotation brings the dorsal mesentery to lie along the posterior abdominal wall. Eventual involution and fusion of the mesentery leaves the lienorenal ligament (LRL) as its remnant. The gastrosplenic ligament (GSL) forms one of the lateral borders of the lesser sac. The gastrohepatic ligament (GHL) persists as the lesser omentum. The falciform ligament (FL) continues to separate the right side of the peritoneum from the left, anteriorly and superiorly, in the subphrenic space.

Figure 113-10 Formation of the greater omentum. **A.** Longitudinal schematic drawing shows the fusion of the two leaves of the greater omentum with obliteration of the inferior recess of the lesser sac. **B.** Fusion of the greater omentum with the transverse colon and its dorsal mesentery gives rise to the definitive gastrocolic ligament and the transverse mesocolon.

ligament ventrally, the caudate lobe of the liver superiorly, the inferior vena cava posteriorly, and a reflection of peritoneum from the pyloroduodenal region inferiorly.⁵²

The spleen develops within the stomach's elongated dorsal mesentery and divides it into two components that contribute to the lateral borders of the lesser sac. The lienorenal ligament represents the fusion of the dorsal portion of the mesogastrium to the retroperitoneum. The gastrosplenic ligament represents the more ventral remnant of the spleen's mesenteric origin between the stomach and the posterior abdominal wall (see Fig. 113-9).⁵²

The raised peritoneal ridge overlying the left gastric artery divides the lesser sac into two compartments. The smaller, medial compartment contains the submerged (subdiaphragmatic) portion of the esophagus. Inflammatory exudate in the medial lesser peritoneal sac may extend transdiaphragmatically through the esophageal hiatus into the mediastinum.

Abnormal Development of the Lesser Sac and Greater Omentum

INFRACARDIAC BURSA

Rarely, a persistent communication exists at the level of the diaphragm, with the medial lesser peritoneal sac extending into the mediastinum. This forms an infracardiac cystic space medial to the right lung.³³

OMENTAL CYST

A mesenchyme-lined omental cyst can develop within the leaves of the greater omentum, representing incomplete obliteration of the inferior recess of the greater omentum. Histologic differentiation of mesenteric, omental, duplication, and neurenteric cysts is based on their cell linings and other wall components.^{53,54}

Normal Development of the Spleen

The spleen develops from the mesenchyme within the mesogastrium during the fifth week of development. Initially, several distinct clusters of mesenchyme are formed. These coalesce and fuse to form the spleen, which develops its characteristic shape by the third month. Their fusion leads to the spleen's lobulated contour. Before birth, the splenic contour smooths; only a few notches remain along its anterosuperior border. The mesenchyme forms the reticular framework, trabeculae, and capsule of the spleen. The T and B lymphocytes arise in the bone marrow and migrate to the spleen. By the fourth month, the spleen is producing megakaryocytes and other blood cell precursors as part of its hematopoietic activity, a capacity that is retained in the adult spleen.

Abnormal Development of the Spleen

ACCESSORY SPLEEN

Accessory spleen refers to congenitally derived ectopic splenic tissue (see Chapter 104). This is separate and distinct from splenosis, which is ectopic splenic tissue resulting from trauma and subsequent implantation and growth of splenic fragments.

Accessory spleens may result from failure of the splenic clusters to fuse.⁵⁵ Alternatively, exaggerated lobulation may cause tissue to be pinched off and separated from the main spleen.⁵⁶ Up to 30% of the population has accessory splenic tissue.^{33,55} It is most commonly found in the splenic hilum, but it may be found elsewhere in the retroperitoneum.⁵⁷ Usually, only one accessory spleen is present. There is an association between having an accessory spleen and hematologic disorders.⁵⁸

WANDERING SPLEEN

The spleen may have an unusual degree of mobility and occupy an atypical location (see Chapter 104) in less than 0.2% of all patients.⁵⁵ It is most commonly found in multiparous women.^{59,60} Wandering spleen has been associated with incomplete fusion or even absence of the gastrosplenic and lienorenal ligaments.^{61,62} Its association with splenomegaly and increased frequency in postpartum women suggests an acquired cause.⁶³ The spleen's exaggerated mobility predisposes it to torsion and subsequent infarction.

ASPLENIA

Isolated absence of the spleen without accompanying abnormalities is usually an acquired condition.^{64,65} However, it occurs more frequently in boys and with a complex constellation of congenital abnormalities of multiple organ systems (see Chapter 122).⁶⁶ One theory suggests a link with maldevelopment of the body curvature in the embryo.⁶⁷ This accounts for the frequent situs abnormalities (especially dextroisomerism) in conjunction with asplenia.⁵⁵

POLYSPLENIA

Polysplenia is a component of a broader heterotaxy syndrome that is defined by a host of anatomic abnormalities. This heterotaxy syndrome is associated with levoisomerism, which suggests the presence of bilateral bilobed lungs and bilateral pulmonary atria. This syndrome is also associated with a central intra-abdominal liver, a randomly located stomach, and multiple spleens. Cardiac anomalies may also be present, but they are more common in asplenic rather than in polysplenia patients. The most common finding in heterotaxy syndrome with polysplenia is azygos (or hemiazygos) continuation of the inferior vena cava, which can be easily detected by cross-sectional imaging as well as on careful scrutiny of lateral plain films of the chest (Fig. 113-11). This constellation of findings in heterotaxy syndrome with polysplenia is not constant, and variations may be found from patient to patient.⁶⁸

As in the case of asplenia, the multiple organ system anomalies associated with polysplenia may be related to abnormal development of the embryo's body curvature.⁶⁷ Polysplenia is more common in females. Although polysplenic patients present with a wider spectrum of clinical manifestations compared with asplenic patients, reportedly more than 50% of those born with this condition die within the first year of life.^{55,69}

SPLENIC-GONADAL FUSION

Splenic-gonadal fusion is almost exclusively seen in boys and involves the left side.^{70,71} Continuous and discontinuous forms are seen with equal frequency. The continuous form involves a

Figure 113-11 Polysplenia with azygos continuation of the inferior vena cava. **A.** Coronal CT scan demonstrating multiple spleens in the left upper quadrant. **B.** Axial CT scan demonstrates azygos continuation of the inferior vena cava in the same patient, a common finding in heterotaxy syndrome with polysplenia.

band of fibrous and splenic tissue connecting the left gonad to the spleen.⁷⁰ Approximately 25% of these patients have cryptorchidism. In the discontinuous form, ectopic splenic tissue is located in the gonad.

The developing gonad arises during the sixth week of embryogenesis from the mesonephros, which is adjacent to the splenic precursor in the dorsal mesentery.⁷² The gonadal tissue normally descends during the eighth week of development. Failure of these two anlagen to separate completely may account for this anomaly.

Normal Midgut Rotation and Fixation

Only anthropoid apes and humans have partial obliteration of the primitive dorsal mesentery. This most likely results from their upright posture.⁷³

During the third and fourth weeks of development, the embryo starts to grow much more rapidly than the yolk sac. By the fifth week, the intraembryonic and extraembryonic celomic cavities connect by a narrow stalk (i.e., omphalomesenteric or vitellointestinal duct or yolk stalk) (see Fig. 113-2).

Within the intraembryonic celom, the midgut starts to elongate and loop ventrally into the yolk sac. This midgut loop can be divided into two segments, originally of roughly equal length. The axis of this loop is the superior mesenteric artery, and its apex is marked by the omphalomesenteric duct. The prearterial segment starts at the foregut-midgut junction and ends at the apex of the loop. This gives rise to the duodenum distal to the papilla, the jejunum, and most of the ileum. The postarterial limb extends from the apex of the loop to the midgut-hindgut junction. From this segment arise the very distal and terminal ileum, cecum, appendix, ascending colon, and most of the transverse colon. The transition to the hindgut is usually in the distal third of the transverse colon, where the changeover from superior mesenteric artery (i.e., middle colic) to inferior mesenteric artery (i.e., left colic) distribution occurs (Fig. 113-12).

By the fifth week, a small swelling (i.e., cecal bud) in the proximal postarterial segment, just distal to the apex of the

Figure 113-12 Intestinal tract development at 6 weeks.

Longitudinal view of the intestinal tract at 6 weeks of development shows that the superior mesenteric artery (SMA) acts as the axis for midgut rotation. The omphalomesenteric duct (OMD) divides the midgut into prearterial and postarterial limbs. Notice the physiologic herniation of the midgut through the umbilical orifice (UO). Heavy lines mark the foregut-midgut (/) and the midgut-hindgut (//) junctions. The celiac axis (CA) is the major artery of the foregut; the inferior mesenteric artery (IMA) supplies the hindgut. CB, Cecal bud.

umbilical loop, marks the beginning of the differentiation between small and large bowel.

The pioneering work of Snyder and Chaffin in the early 1950s prompted a major revision of the theory of how the midgut rotates.^{74,75} The herniation of the midgut takes place in

the sixth week of development. It is limited by dense condensations of the dorsal mesentery that bind the more proximal prearterial and more distal postarterial segments to the posterior peritoneum.⁷⁶ Within this hernia, the midgut markedly elongates. The growth predominantly involves the prearterial segment. Pressure from the enlarging right lobe of the liver, along with the rapid elongation, forces the prearterial segment down and to the right.^{33,76} The increase in length is accommodated by a series of convolutions and small loops. At this point, the postarterial segment occupies the left side of the umbilical hernia. Viewed from the front, this represents a 90-degree counterclockwise rotation.

By the 10th week, further growth in the peritoneal cavity and less rapid increase in the liver size allow sufficient room for the physiologic herniation of the midgut to reduce itself. First to return is the elongated, convoluted prearterial limb.^{33,74-76} These right-sided (originally cranial) loops enter the abdomen on the right side of the superior mesenteric artery but then pass behind that artery to occupy the left side of the abdomen. The now larger cecal bud may impede the return of the postarterial (originally caudal), now left-sided midgut until the prearterial return is complete (Fig. 113-13).³³

During the 11th week, the more slowly growing postarterial segment returns. As the herniation is reduced, the colon continues to rotate, first in front of and then to the right of the

superior mesenteric artery (Fig. 113-14). By the 12th week, the colon completes a 270-degree counterclockwise rotation. These 270 degrees comprise 90 degrees occurring during the umbilical herniation and an additional 180 degrees during its reduction. Flexion of the embryo carries the cecum to the level of the iliac crest. Its final, right lower quadrant position is a result of the continued growth of the ascending colon, not further midgut rotation.³³

The development of the appendix is a separate and distinct process.⁷⁷ Differential rates of growth between the base of the primitive cecum and its apex result in the rapid formation of a vermiform appendage, the appendix. Asymmetric growth of the lateral wall of the cecum after birth causes the appendix to migrate from the midline to the same side of the cecum as the ileocecal valve. The growth of the medial wall may be hindered by the presence of the ileum and its vascular pedicle.⁷⁷

From the 11th week to the end of the 5th month, a gradual, partial resorption of the dorsal mesentery occurs. The segments attaching the ascending and descending colon agglutinate with the parietal peritoneum of the posterior abdominal wall, leading to their final, so-called retroperitoneal location. In reality, they are usually covered by peritoneum on their anterior, medial, and lateral borders; only their posterior walls are truly retroperitoneal.

Figure 113-13 Intestinal tract development at 10 weeks. Frontal view of a 10-week fetus. The elongated, redundant prearterial limb has re-entered the abdomen and crossed to the left of and behind the superior mesenteric artery (SMA). This displaces the hindgut to the left. Heavy lines mark the foregut-midgut (/) and the midgut-hindgut (/) junctions. CB, Cecal bud; OMD, omphalomesenteric duct; UO, umbilical orifice.

Figure 113-14 Intestinal tract development at 11 weeks. With development 1 week later than in Figure 113-13, reduction of the physiologic herniation is complete. The postarterial limb has partially completed its 180-degree rotation, and the cecum lies in the upper abdomen on its way to the right side. CB, Cecal bud; SMA, superior mesenteric artery.

The transverse colon mesentery (i.e., mesocolon) persists into adulthood. It partially fuses with the greater omentum, forming the gastrocolic ligament. The distal end of the transverse mesocolon (i.e., phrenicocolic ligament) serves as an anchor that fixes the splenic flexure in the left upper quadrant. It also seals the left paracolic gutter, preventing the spread of disease into the left upper quadrant from below.^{36,78}

In the small bowel, the thick proximal attachment of the prearterial segment lies to the left of the second lumbar vertebra, marking the duodenal-jejunal junction. This dorsal mesenteric remnant of the duodenum is also resorbed into the posterior abdominal wall, which results in “retroperitonealization” of the duodenum. The distal end of the small bowel mesentery is carried into the right lower quadrant, ending at the level of the fourth or fifth lumbar vertebra. The mesenteric small bowel is suspended from a short posterior attachment along the posterior abdominal wall.

The sigmoid colon maintains its dorsal mesenteric attachment as the sigmoid mesocolon. Its short length compared with the variable length of attached colon may contribute to the development of sigmoid volvulus.

Abnormal Midgut Rotation and Fixation

DUPLICATION

A second intestinal lumen may form parallel to the primary one because of errors in recanalization.^{33,54,79} The duplication does not usually communicate with the primary lumen, but they share a common muscle wall and blood supply. They are more often found in the ileum (see Chapter 117).^{33,53}

ILEAL ATRESIA

Atresias of all levels of the small bowel from duodenum to ileum have been attributed to in utero ischemic processes (see Chapter 117).^{80,81} Other authorities implicate intrauterine inflammatory disease in cases of multiple intestinal atresias.⁸²

MESENTERIC CYST

Cysts within the mesentery have various origins. Their differentiation depends on the histologic determination of their wall constituents and lining cells.^{53,54}

NONROTATION

Although commonly called malrotation, nonrotation represents an abnormal arrest of the midgut rotation after the first 90 degrees of rotation.^{33,54,83} At this point, the prearterial midgut lies to the right of the superior mesenteric artery, and the postarterial limb lies to the left. The postarterial limb is then first to return to the abdomen. Consequently, it lies in the left hemiabdomen. The returning prearterial segment is forced to remain on the right (Fig. 113-15). Both segments continue to share a common dorsal mesentery, which lies in the midline. This allows considerable mobility of the small and large bowels and predisposes to midgut volvulus.

REVERSED ROTATION

In the rare entity of reversed rotation, the order of the midgut return is reversed, with the postarterial limb preceding

Figure 113-15 Nonrotation of the gut. A. Single-contrast barium enema shows that the entire colon lies in the left hemiabdomen. This reflects the premature return of the postarterial limb of the midgut after the first 90 degrees of rotation. **B.** An upper gastrointestinal series in the same patient demonstrates incomplete formation of the duodenal sweep. The jejunum and most of the small bowel lie in the right hemiabdomen. The prearterial limb of the midgut must remain on the right after the postarterial limb occupies the left.

the prearterial.^{33,54} This causes the colon to lie posterior to the superior mesenteric artery; the duodenum and small bowel cross anteriorly. Abnormal mesenteric bands may cause obstruction.

INCOMPLETE ROTATION AND MALFIXATION

Although rotation and fixation are two separate and distinct stages of development, abnormalities of rotation are frequently associated with malfixation.^{33,54,73,83} Most often, the colon fails to complete its final 180-degree rotation, ending in the right upper quadrant. There may be incomplete resorption of the dorsal mesentery that allows formation of elongated and mobile segments of colon. Many different variations and combinations of abnormal rotation and fixation may be encountered. The presence of an abnormally rotated proximal limb does not necessarily imply an abnormally rotated lower tract, but the presence of an abnormal lower tract is almost always associated with abnormal proximal rotation.

Multiple congenital anomalies of the gastrointestinal tract and other organ systems have been reported with abnormal intestinal rotation and fixation.⁸³ Duodenal atresia or web (11%) was the most common associated anomaly, followed by Meckel's diverticulum (11%), omphalocele (9%), other stenosis or atresia (5%), and Hirschsprung's disease (2%). Less common associated anomalies included cardiac and orthopedic anomalies, biliary atresia, pancreatic anomalies, microcolon, esophageal webs, and tracheoesophageal fistula.^{84,85}

HYPERROTATION

In hyperrotation, an elongated colon continues to rotate past its usual 270-degree stopping point.^{33,54} The cecum may cross the midline, sometimes reaching the left upper quadrant. Because the prearterial segment is normal in length and rotation, it lies in its normal position and is not affected in this entity.

INTERNAL HERNIATIONS

Abnormalities in the formation and resorption of the dorsal mesentery may allow fossae to develop into which loops of bowel may herniate (see Chapter 112). The most common of these fossae are those near the duodenum.^{33,54}

Left paraduodenal hernias are much more common than those on the right. The fossa of Landzert is formed by incomplete fusion of the descending colon mesentery.⁵⁴ Bowel loops may herniate under the colon and in front of the inferior mesenteric vein. A similar defect in the small bowel mesentery (i.e., fossa of Waldeyer or mesentericoparietal fossa) allows loops to herniate from the left upper quadrant beneath the superior mesenteric artery to the right.⁵⁴ This is a right paraduodenal hernia.

Similar but less common defects may exist in the periceal region, within the sigmoid mesocolon, and even in the transverse colon mesentery. Many different types and positions of internal herniations may be seen in these areas.

MECKEL'S DIVERTICULUM

If the omphalomesenteric duct fails to be completely obliterated, a persistent outpouching of the bowel may persist. Its

Figure 113-16 Meckel's diverticulum. Coned-down view from an enteroclysis shows Meckel's diverticulum (arrow) arising from the antimesenteric border of an ileal loop. This represents the remnant of the omphalomesenteric duct.

location at the apex of the physiologic herniation accounts for the location of Meckel's diverticula in the distal ileum (see Chapter 117).

Meckel's diverticulum has a wide spectrum of variation.⁵⁴ There may be cystic remnants between the small bowel and the umbilicus or fibrous bands. Communication with the bowel is the most common finding (Fig. 113-16), but draining umbilical sinuses also have been reported. The fibrous cord may act as an axis of rotation, allowing volvulus to develop.

These diverticula can contain ectopic gastric or pancreatic tissue. The presence of ectopic gastric tissue may lead to peptic ulceration and bleeding. Rare neoplasms have been reported within the mucosal lining. Stasis of intestinal contents within the diverticulum may give rise to enterolith formation. Rarely, the diverticulum may invert and act as the leading edge of an intussusception. In Littre's hernia, the diverticulum enters a hernia sac.⁵⁴ Some studies have demonstrated an increased incidence of Meckel's diverticulum in patients with known Crohn's disease. Meckel's diverticula were found in 17 (5.8%) of 294 patients with Crohn's disease, a rate that is about two to three times greater than in the general population.⁸⁶ In another study, however, only 10 (1.1%) of 877 patients with Crohn's disease had Meckel's diverticula.⁸⁷ Most patients with Crohn's disease and associated Meckel's diverticula were younger than 40 years and had ileal involvement with or without colonic involvement.⁸⁷ This study concluded that the overall presence of Meckel's diverticulum is not increased from that in the general population, and more important, the presence of Meckel's diverticula did not alter patient management.⁸⁷ In these studies, none of the patients with surgically proven Meckel's diverticula had heterotopic gastric mucosa. This finding implies that imaging with technetium in these patients would not yield positive results.^{86,87}

ACKNOWLEDGMENT

The authors wish to acknowledge the significant contributions of James H. Sloves, MD, and Joseph Patrick Mazzie, DO, in the preparation of this chapter.

This chapter discusses gastrointestinal malformations that are manifested during the neonatal period. Some are grossly apparent at birth (e.g., gastroschisis, omphalocele, diaphragmatic hernia); others usually are manifested within the first hours or days of life (e.g., esophageal, small bowel, or colonic atresia; meconium ileus; meconium plug; Hirschsprung's disease). Many of these diagnoses can be suggested by prenatal ultrasound.

Rotational Anomalies**EMBRYOLOGY**

During the sixth gestational week, rapid elongation of the midgut and hindgut results in their herniation into a sac in the midline of the anterior abdominal wall. Before returning to the peritoneal cavity during the ninth week of gestation, the midgut revolves 90 degrees around the superior mesenteric artery. Once it is within the abdominal cavity, the bowel rotates

an additional 180 degrees, which positions the duodenojejunal junction to the left of the spine at the level of the stomach, the jejunum in the left upper quadrant, and the ileum in the right hypochondrium or right lower quadrant.¹⁻³ The colon undergoes a separate counterclockwise rotation of 270 degrees, which brings the cecum into the right lower quadrant. This normal rotation is associated with a broad mesenteric base, extending from the left upper quadrant to the right lower quadrant. Attachments at two sites keep the bowel fixed in proper position: the ligament of Treitz at the duodenojejunal junction and an attachment at the cecal base.

Deviation from normal rotation and fixation occurs universally in children with omphalocele, gastroschisis, and diaphragmatic hernia. Variations of rotation may also be present in children with asplenia and polysplenia syndromes, duodenal stenosis or atresia, and Hirschsprung's disease. However, malrotation frequently exists as an isolated anomaly.

The spectrum of rotational abnormalities is broad (Figs. 114-1 to 114-3).³⁻¹⁰ In some children, the process of rotation

takes place, but fixation fails to occur. In others, there are only minor variations from the normal position. Complete nonrotation is said to be present when the jejunum is to the right of the spine and the ileum is in the pelvis or to the left of the spine. Most clinical problems arise in children with the greatest deviation from the normal rotational pattern. In classic malrotation,

the cecum lies in the midabdomen or left of the midline (see Fig. 114-2) and may be fixed in place by broad bands that emanate from the undersurface of the liver. These Ladd bands cross the duodenum and may cause extrinsic compression and obstruction of the gut at this level (see Fig. 114-3).

CLINICAL FINDINGS

Most children with malrotation present in the first few months of life. They have acute abdominal symptoms if there has been acute volvulus with twisting of the bowel on its shortened mesentery or chronic vomiting and failure to thrive because of the obstructing Ladd bands (see Fig. 114-3). Midgut volvulus may produce vascular compromise, which can lead to gangrene of the entire small bowel if it is not promptly diagnosed and treated (Fig. 114-4).⁴⁻¹⁰

In some children, malrotation is not detected until later, when studies are done for other purposes. Uncommonly, malrotation can be associated with chronic volvulus. This condition interferes with lymphatic and venous drainage, which produces malabsorption or failure to thrive.¹¹⁻¹⁴ Acute volvulus with infarction of bowel does occur, although rarely, in older children and adults. Motility abnormalities may persist after corrective surgery. Other duodenal abnormalities occur frequently in children with malrotation: duodenal atresia, annular pancreas, and preduodenal portal vein.

RADIOLOGIC FINDINGS

Abdomen radiographs are of little value in the child with an uncomplicated rotational abnormality because the positions of the duodenojejunal junction and cecum are rarely definable without positive contrast media. Sometimes, abnormal configuration of the gas in the right hypochondrium (i.e., duodenal triangle) may suggest the diagnosis of malrotation with volvulus.¹¹ Normal findings on radiographs do not exclude the diagnosis of malrotation with volvulus.^{4-6,10}

Figure 114-1 Rotational variation. The duodenal bulb overlies the spine, and multiple jejunal loops are seen throughout the right side of the abdomen.

Figure 114-2 Malrotation demonstrated on barium enema. **A.** The cecum (C) lies in the left lower quadrant. Contrast medium is visible in the appendix (arrows). **B.** In a different child, the cecum (C) is in the left upper quadrant.

Figure 114-3 Malrotation with Ladd bands. This upper gastrointestinal series shows a partially obstructing, extrinsic defect (arrow) in the duodenum.

In the neonate or child with abdominal pain or vomiting, abdomen radiographs showing gaseous distention of the stomach and duodenal bulb suggest a high obstruction (see Fig. 114-4). This appearance (i.e., double bubble) can also be seen in duodenal atresia and annular pancreas. A contrast study may be necessary for differentiation between the relatively benign complication of Ladd bands (see Fig. 114-3) and the surgical emergency of volvulus (see Fig. 114-4).

In the child with midgut volvulus, the abdominal gas pattern may be normal or show high or low obstruction, or the abdomen may be gasless.⁵⁻⁷ Because abdomen radiographs are usually nondiagnostic and the consequences of delayed diagnosis are grim, contrast studies should be performed emergently when volvulus is suspected.

The first study performed to detect the malrotation and its complications should be an upper gastrointestinal series. The barium enema can show a malpositioned or malfixed cecum (see Fig. 114-2), but normal results of a barium enema do not exclude malrotation with volvulus. For this reason, an upper gastrointestinal series may need to be performed after the enema if a low obstructive lesion is not found and malrotation is still considered.

The diagnosis of malrotation can be made sonographically, although it is usually an incidental finding on studies performed for other reasons.^{14,15} Failure of the bowel to rotate normally produces an abnormal relationship between the superior mesenteric artery and vein. With volvulus, the superior mesenteric vein may wind around the superior mesenteric artery, inconsistently producing the whirlpool sign on ultrasound.¹⁵ Sonography may exclude malrotation by showing the third portion of the duodenum between the aorta and superior mesenteric artery.^{16,17} Computed tomography (CT) can also show these vascular changes and demonstrate malpositioned and twisted bowel.¹⁸

Figure 114-4 Midgut volvulus. Plain radiograph demonstrates air only in the stomach and duodenum in this acutely ill infant with midgut volvulus.

Gastroschisis

GENERAL CONSIDERATIONS

Development of the anterior abdominal wall is complex, with the orderly ingrowth of four separate folds (i.e., cranial, caudal, and two lateral) necessary for normal closure.^{19,20} Gastroschisis is a parasagittal defect, usually to the right of the normally positioned and normal-appearing umbilical cord, through which bowel herniates into the amniotic fluid.

CLINICAL FINDINGS

The herniated bowel has no covering membrane or sac and is therefore associated with a rise in the maternal serum α -fetoprotein level. Occurring in about 1 of 10,000 live births, gastroschisis can be diagnosed prenatally with sonography.²¹⁻²³ At birth, the defect and herniated bowel are apparent and not easily confused with other abdominal wall defects.

Malrotation or nonrotation of the bowel is the rule in gastroschisis, but it rarely leads to complications. Bowel atresia, present in 20% of cases, is usually the only anomaly, but it is an important factor contributing to postoperative morbidity.²⁴⁻²⁸

TREATMENT

Even though a small amount of bowel usually is herniated through a small defect, surgical repair is associated with a postoperative mortality rate of 5% to 25%, with major complications of sepsis and electrolyte problems.²²⁻²⁹ Antenatal exposure

to amniotic fluid produces bowel wall edema and inflammatory thickening of the serosa, which interferes with peristaltic function, even after repair.²⁸ In utero, the exposed bowel and mesentery may become shortened and coiled, which also affects postnatal function. Short gut syndrome may decrease intestinal absorption and cause diminished constitutional growth. Children with short gut or hypoperistalsis can be supported with parenteral hyperalimentation, but this also can create management problems: venous thrombosis, liver disease, and cholelithiasis. Cesarean section, once routine in an attempt to diminish the intrauterine bowel changes, has been shown to produce no difference in postnatal and postoperative bowel function.^{20,23,29}

The type of surgical correction, primary or delayed, depends on the size of the defect and the presence of other complications, such as atresia and short gut.²⁶⁻²⁹ In addition to covering the herniated bowel, with placement of an abdominal silo, it may be necessary to create a stoma to decompress the dilated bowel proximal to an atresia.

After surgery, motility changes are universal in children with gastroschisis.²⁷⁻³¹ The initial postoperative paralytic ileus is frequently followed by marked prolongation of intestinal transit. These children also have a high incidence of significant gastroesophageal reflux. Even though they are usually term infants, necrotizing enterocolitis (NEC) occurs in 23% of cases at 1 to 4 months after repair and may be manifested atypically; only 36% of affected children have blood-streaked stool.³⁰

RADIOLOGIC FINDINGS

The prenatal sonographic diagnosis of gastroschisis is based on the observation of normal umbilical cord insertion in a fetus with an anterior abdominal wall defect through which bowel has herniated.^{19,21,23} No membrane covers the bowel; if fetal ascites or a covering membrane is present or if the liver is detected in the herniated viscera, omphalocele is the more likely diagnosis.^{19,22,32} Thickening of the exteriorized bowel loops strongly suggests gastroschisis. Amniotic fluid volume is usually normal. A bowel caliber of more than 17 mm suggests that an atresia is present; similarly, bowel of a smaller diameter is usually associated with bowel continuity.

Abdomen radiographs show the normally positioned umbilical clamp separated from herniated bowel loops, which are outlined by air (Fig. 114-5). Postoperative radiographs should be scrutinized to detect changes of NEC: ileus, dilated bowel loops, and intramural air.^{27,30} Postsurgical barium studies are used to detect gastroesophageal reflux, bowel loop dilation, obstructive adhesions, amount of bowel present, and abnormalities of position, peristalsis, or transit time.³³

Omphalocele

CLINICAL FINDINGS

Omphalocele, present in about 1 of 5000 live births, is a midline defect of variable size through which bowel, liver, spleen, pancreas, and uterus may protrude.^{19,21,32} A membrane or sac usually covers the herniated organs, but the sac may be ruptured at birth. The umbilical cord inserts into the apex of the sac. The bowel is malrotated, and 8% to 20% of these children have Meckel's diverticulum.

The diagnosis of omphalocele can be made with prenatal ultrasound.^{19,21,22,32} Maternal α -fetoprotein levels may be

Figure 114-5 Gastroschisis. Exteriorized bowel loops (white arrows) extend lateral to the abdominal wall in this neonate with gastroschisis. Because the loops lack a covering membrane, each is clearly outlined by air. The normally inserted umbilical cord is in the midline, defined by the umbilical clamp to the left of midline (open arrows).

elevated, but because of the covering sac, they tend to be less than those found with gastroschisis. Associated anomalies are seen in about 50% to 80% of infants with omphalocele, including tetralogy of Fallot and atrial septal defect as well as other cardiac, central nervous system, and gastrointestinal anomalies. Detection of anomalies may influence the outcome or management of the pregnancy; certain anomalies are associated with fetal demise, and others may result in planned termination of pregnancy.³⁴⁻³⁶ Children with Beckwith-Wiedemann syndrome account for almost 12% of the population with omphalocele. These infants are large at birth and have a large tongue. A specific pancreatic abnormality, nesidioblastosis, predisposes the infants to hypoglycemia, even in the neonatal period. Down syndrome (i.e., trisomy 21), trisomy 13, and trisomy 18 are associated with an increased incidence of omphalocele.^{32,34-36}

Children with small anterior abdominal defects (e.g., gastroschisis, small omphalocele) tend to have a normally developed thorax. Those with giant omphaloceles (i.e., containing liver and bowel) have a small thorax and an increased incidence of pulmonary hypoplasia and respiratory insufficiency. They may require ventilatory support after surgery.^{36,37}

Surgical management may take many forms.³⁸ In most children, the defect is corrected by primary skin closure or closure with a silo. The surgical approach is determined by the size of the defect, and larger defects may require a staged reduction.

RADIOLOGIC FINDINGS

Prenatal sonographic diagnosis of omphalocele is based on visualization of the umbilical cord inserting into the membrane covering structures anterior to the abdominal wall of the fetus.^{19,21-23,32,35} Fetal ascites, abnormal amounts of amniotic fluid, and associated congenital defects are supportive ancillary

Figure 114-6 Omphalocele. Lateral abdomen radiograph reveals a membrane-covered omphalocele. The sac of the omphalocele is outlined by air and clearly seen, but individual bowel loops cannot be identified because they are not exposed to air, unlike the situation in gastroschisis. The air-filled stomach (S) protrudes into the omphalocele.

findings. Thickening of exteriorized bowel loops or absence of membrane or sac suggests the diagnosis of gastroschisis.

Postnatal abdominal radiographs (Fig. 114-6) depict the omphalocele as a soft tissue density whose margins are well defined by the adjacent air. Unlike gastroschisis (see Fig. 114-5), the bowel loops are not individually seen unless the omphalocele sac has ruptured. Malrotation of the bowel and malposition of other organs are identified on postoperative imaging studies.³⁹

Diaphragmatic Hernia

FORAMEN OF BOCHDALEK HERNIA

Embryology

In early fetal life, the peritoneal cavity and the pleural space are in continuity. At week 8, just before anteriorly herniated bowel returns to the abdominal cavity, the communication between these two spaces is closed by the development of the diaphragm.⁴⁰ If the bowel returns to the abdomen prematurely or if the diaphragm develops late or incompletely, a diaphragmatic hernia develops. Affected children have malrotation of the bowel because the normal rotation that occurs as the bowel returns to the abdomen is interrupted. A membrane covers the herniated gut in only 10% of Bochdalek hernias.

Clinical Findings

The posterolateral or Bochdalek hernia occurs in approximately 1 of 3000 live births.⁴⁰ Some diaphragmatic hernias may be acquired after trauma or infection. In the neonatal period, diaphragmatic hernias can develop in association with group B streptococcal infection.⁴¹ Late presentation or detection of an asymptomatic diaphragmatic hernia has also been described.^{41,42}

Congenital diaphragmatic hernia occurs six to nine times more often on the left, presumably because the pleuroperitoneal

canal closes earlier on the right; about 3% of children have bilateral diaphragmatic hernia. Left-sided hernias usually contain portions of the gastrointestinal tract. The liver may extend into the thorax with left or right diaphragmatic hernias. Regardless of the side on which the hernia occurs, the ipsilateral and contralateral lungs are compressed, and the most critical factor in determining the neonate's outcome is the degree of pulmonary hypoplasia.⁴³⁻⁴⁸

Diaphragmatic hernia should be suspected clinically when a neonate with severe respiratory distress has a scaphoid abdomen. Because bowel contents are in the thorax, the abdomen lacks its normal protuberant appearance. Most newborns with diaphragmatic hernia are rapidly intubated and resuscitated; when they are stable, they undergo surgical repair. All children are carefully inspected for midline defects (i.e., cleft lip and palate, spina bifida, and omphalocele) and cardiac lesions (i.e., ventricular septal defect and tetralogy of Fallot) because associated anomalies also determine outcome.^{42,43}

Despite ventilatory support and pharmacologic manipulation including inhaled nitric oxide to correct pulmonary hypertension, a common complication of diaphragmatic hernias, early presurgical mortality rates range from 20% to 80%.⁴³ To improve survival, extracorporeal membrane oxygenation (ECMO) is used in infants who experience significant respiratory insufficiency resulting from pulmonary hypoplasia.^{48,49} ECMO may be performed before, during, or after surgery. This lung bypass system entails placement of large-bore cannulas into the aortic arch through the right common carotid artery and the right atrium (venoarterial approach) or a single double-lumen catheter into the right atrium (venovenous approach) through the right internal jugular vein.⁵⁰ Heparinization is routine. The lungs are minimally ventilated and given the chance to mature and grow. ECMO has increased postsurgical survival to more than 80%, but it is not without complications: bleeding at the neck wounds, intracerebral and pleural hemorrhage, and difficulty with later central line placement. Children who require ECMO have a poorer neurologic outcome than those who do not. Because these children are sicker from the moment of birth, the neurologic deficits have a multifactorial cause, including ECMO.⁵¹

The fact that many infants with diaphragmatic hernias still died before undergoing repair drove the research in prenatal surgical intervention throughout the 1990s. The observed-to-expected fetal lung volume measured by magnetic resonance imaging (MRI) is reported to be a predictor of survival.⁴⁴ In fetuses with a very low observed-to-expected fetal lung volume, one fetal surgical technique employed involves fetal tracheal occlusion; this causes fluid to fill the lungs and encourages their expansion despite the extrinsic pressure produced by herniated abdominal contents.⁵² The clip or balloon occluding the trachea is removed at the time of birth, allowing normal respiration. Results with this technique, used only in those whose prenatal ultrasound indicates severely compromised lung parenchyma, have been promising.⁵²

Radiologic Findings

The prenatal sonographic diagnosis of diaphragmatic hernia is made when the heart and other mediastinal contents are shifted from the midline and a "mass" (i.e., liver or gut) is present in the thorax.^{40,43-45} A fetal abdominal circumference below the fifth percentile correlates with a poor prenatal and postnatal course in some studies.⁵³ Fetal ascites, pleural effusion, and

polyhydramnios have been associated with diaphragmatic hernia.

Prenatal ultrasound and MRI have documented the presence of a portion or all of the liver in many diaphragmatic hernias.^{44,47} When it is not diagnosed prenatally, the affected infant presents with respiratory distress shortly after birth. Abdomen radiographs can determine the amount of bowel present in the abdomen. Chest radiographs can exclude other causes of neonatal respiratory distress: pulmonary immaturity, congenital pulmonary airway malformation, and pneumonia. Complications of resuscitation and other congenital abnormalities that may affect management should be sought. Pneumothorax is common and requires prompt treatment.

On early radiographs, the herniated bowel loops may appear as a soft tissue mass. With time and air swallowing, the chest radiographs have a more typical bubbly appearance (Fig. 114-7). Diaphragmatic hernias that contain liver may appear more solid and may be accompanied by a pleural collection. On occasion, mild diaphragmatic hernias are not diagnosed until later in childhood.⁴⁰

If the nature of the thoracic contents is uncertain, a nasogastric tube should be inserted to define the stomach and to introduce air into the bowel. Contrast studies are rarely needed to visualize the upper or lower gastrointestinal tract before surgery (Fig. 114-8).

The mediastinum remains shifted to the side opposite the hernia on immediate postoperative chest radiographs. The ipsilateral lung appears as a soft tissue density outlined with air close to the mediastinum. The ipsilateral pneumothorax is expected and may simulate tension pneumothorax because of the long-standing mediastinal shift. Attempts to evacuate this pneumothorax may result in overexpansion of the hypoplastic

contralateral lung and cause contralateral pneumothorax. During the first few postoperative days, as the ipsilateral lung expands, fluid may occupy a portion of the pleural space and produce haziness on that side of the thorax.

Before a child is placed on ECMO, cardiac, cranial, and abdominal ultrasound is performed to identify those who can safely receive this treatment. Neonates with intracranial hemorrhage or with a lethal anomaly are excluded from ECMO.

Neonates treated with ECMO receive a daily chest radiograph. Evaluation of line placement is necessary; kinking and dislodgment of support lines may occur and compromise treatment. Lung opacity is often diffusely increased because of the planned underventilation, increased fluid in the lungs, and, uncommonly, bleeding.^{54,55} Pleural hemorrhage develops in about 30% of children on ECMO and may be manifested as a typical pleural collection or, when it is associated with pneumothorax, an unexpected mediastinal shift.⁵⁵ The esophagus may appear as a mediastinal air or fluid mass in the midline because it frequently dilates from gastroesophageal reflux.⁵⁶ Although the replacement of the bowel loops into the abdomen usually is well tolerated, about 20% of long-term survivors experience intestinal obstruction, and about 13% require surgery for relief of the obstruction.⁵⁷

The most striking finding on the chest radiographs of many long-term survivors is the degree to which the hypoplastic lungs may grow and develop. In many children, a chest radiograph at age 2 or 3 years has a nearly normal appearance.⁵⁸

FORAMEN OF MORGAGNI HERNIA

Herniation of colon or other abdominal structures into the retrosternal space is rare and occurs when the anteromedial aspect of the diaphragm develops abnormally. The so-called foramen of Morgagni hernia accounts for about 2% to 4% of all diaphragmatic hernias.^{40,43,59}

Respiratory and gastrointestinal complaints are common but not necessarily related to the hernia.^{59,60} The child may be asymptomatic, and the abnormality may be detected on a chest radiograph obtained for a nonrelated purpose. Only 50% are detected by age 5 years.⁶¹

Although the amount of bowel herniated into the chest in Morgagni hernias is usually much less than in Bochdalek hernias, malrotation or malfixation is common. In contrast to Bochdalek hernias, Morgagni hernias usually are right sided and have a covering or sac.^{62,63}

The differential diagnosis of air-containing Morgagni hernias includes pneumonia, atelectasis, pneumatocele, abscess, and congenital pulmonary airway malformation. If the liver is herniated, the solid appearance may simulate a tumor of the diaphragm, a pericardial mass, or an anterior mediastinal mass. Morgagni hernias are corrected even in asymptomatic children because of the potential for incarceration and strangulation.

Radiologic Findings

Anteroposterior chest radiographs may show a soft tissue opacity or air along the heart border (Fig. 114-9). On the lateral projection, the anterior location of the hernia and visualization of bowel establish the diagnosis. In some cases, additional imaging may be needed to identify the nature and extent of the hernia (see Fig. 114-9).⁶³

Figure 114-7 Left Bochdalek hernia. Multiple, air-filled bowel loops fill the left thorax and right apex. The mediastinum is shifted to the right, and the soft tissues of the heart and the hypoplastic right lung merge.

Figure 114-8 Right Bochdalek hernia. Frontal (A) and lateral (B) radiographs show a posterior soft tissue density with a focal air collection. This simulates a congenital pulmonary airway malformation or pneumatocele. C. Upper gastrointestinal study reveals that the stomach has herniated into the right thorax. Air-filled small bowel is also in the hernia (arrows).

Normal and Abnormal Neonatal Bowel Gas

With the first breath, the neonate begins to aerate the respiratory and gastrointestinal tracts. Unless there is obstruction, these processes tend to parallel each other. Several problems delay the passage of air into the gastrointestinal tract. The most obvious is a mechanical obstruction in the oral cavity or esophagus, most often esophageal atresia. Drugs given during labor and delivery can depress the swallowing mechanism, diminish the amount of air swallowed, and delay passage of air distally into the small bowel and colon.

Abdomen radiographs that are initially normal but then become gasless raise the possibility that the neonate has sepsis, has developed electrolyte imbalance, is receiving gastric suction, or is being paralyzed while being ventilated. These processes decrease the amount of air swallowed and the amount available for passage into distal bowel.

The bowel gas pattern should be carefully scrutinized in any neonate with respiratory or gastrointestinal symptoms. Gas should be symmetrically distributed throughout the abdomen in a mosaic pattern. Paucity or malposition of the gas may confirm a suspected diaphragmatic hernia. An abdominal mass may displace bowel loops and, through pressure on the

diaphragm, cause respiratory distress. With a high bowel obstruction, a few loops of bowel in the upper abdomen are distended with air and fluid (Fig. 114-10). With distal obstruction, dilated bowel loops fill the abdomen (Fig. 114-11).

In the neonate, it may be difficult to differentiate small from large bowel because haustra are poorly developed. Although location may allow differentiation of small from large bowel, distended small bowel may fill the space usually occupied by the colon or even simulate a distended stomach.

It is important to determine the most distal extent of air because the differential diagnosis depends on the level of the obstruction. Additional views may be necessary to detect air within the colon. Prone lateral rectal views may be useful if an extremely distal lesion is suspected. A contrast study of the colon may be performed to determine if there is an obstruction or to identify the level and nature of the obstruction.

Abdominal Masses

CLINICAL FINDINGS

The differential diagnosis of abdominal mass in the newborn is extensive: ovarian cyst or tumor, alimentary tract duplication, mesenteric or omental lymphangioma, cyst or tumor of the

Figure 114-9 Foramen of Morgagni hernia.

A. Anteroposterior chest radiograph shows an air collection at the left lung base, and there is cardiac dextroposition. **B.** On the lateral view, bowel extends from the abdomen to the retrosternal space. **C.** Barium enema opacifies the colon segments that occupy the anterior portion of the left thorax.

spleen or liver, choledochal cyst, cystic meconium peritonitis, hydrometrocolpos, and retroperitoneal masses.^{60,64-67} Most neonatal abdominal masses originate in the kidneys; ureteropelvic junction obstruction and multicystic dysplastic kidneys are the most common causes. Gastrointestinal lesions account for 8% to 15% of neonatal abdominal masses.

The mass may be detected by prenatal sonography or by abdominal palpation after birth. In some neonates, the mass is sufficiently large to distend or distort the abdominal wall and cause respiratory distress. Ascites may be present or simulated. Pain or obstruction results if the mass is producing pressure on an adjacent structure or if there is torsion of the mass.

A bruit over the liver in an infant with congestive heart failure suggests a hepatic hemangioma. If a mass is present over

the buttocks, the abdominal mass may represent internal extension of a sacrococcygeal teratoma.⁶⁶

RADIOLOGIC FINDINGS

Abdomen radiographs may show obstruction or displacement of bowel, relatively nonspecific findings. Calcifications suggest meconium peritonitis, teratoma, and hepatoblastoma; spinal anomalies suggest anterior sacral meningocele, obstructed cloacal deformity, and sacrococcygeal teratoma with an internal component.

Ultrasound is the premier imaging technique for abdominal and pelvic masses in neonates (Fig. 114-12).^{60,65,66} The following questions should be addressed:

Figure 114-10 High obstruction. Anteroposterior (A) and lateral (B) abdomen radiographs in a child with jejunal atresia show several markedly distended bowel loops that fill the abdomen. The calcification along the anterior abdominal wall (arrows) indicates prior bowel perforation and meconium peritonitis.

Figure 114-11 Low obstruction. Colonic obstruction from Hirschsprung's disease has produced dilation of multiple bowel loops throughout the abdomen. Because discrete haustral markings cannot be identified, it is difficult to appreciate that the colon is dilated in addition to the entire small bowel.

From what compartment or organ does the mass originate?

Is the mass solid, cystic, or septate?

Is there a wall, membrane, or capsule around it?

Do the structures surrounding the mass look normal?

Is there ascites?

Are there any sites of spread or extension within the abdomen or retroperitoneum?

On the basis of the information obtained, the child may proceed to surgery, undergo further radiologic evaluation, or be observed and restudied after a period of observation.

Necrotizing Enterocolitis

CLINICAL FINDINGS

NEC is a life-threatening process that primarily affects the gastrointestinal tracts of premature infants. Signs and symptoms of NEC usually develop in the first 2 weeks of life: rising gastric residual volume, abdominal distention, bloody stools, lethargy, and even changing respiratory status.^{68,69}

Associations other than prematurity have been noted: bowel ischemia of any cause; abnormal gut hormones, immunoglobulins, or peristalsis; enteral feedings, especially high volumes of formula with high calorie concentration; and maternal cocaine use.^{70,71} The occasional epidemic nature of NEC indicates that a viral or bacterial agent may play a role in some cases.

Pathologic examination reveals ulceration that begins in the mucosa and extends to the submucosa; inflammatory cells may be present in multiple bowel layers.⁷² Pneumatosis intestinalis is seen in the submucosa and subserosa. In 50% of cases, normal areas of bowel are interposed between diseased segments. Inflammatory pseudomembranes occur in less than 10%. Many specimens concurrently show acute changes and reparative changes in the same bowel segment. Complications of these processes include gangrene, perforation with peritonitis or enterocyst formation or stricture formation, enteric fistulas, and sepsis.⁷²⁻⁷⁴

Timing of surgery is crucial; ideally, surgery should take place when necrosis is present but before bowel perforation. Erythema of the abdominal wall or positive result of paracentesis suggests bowel perforation and mandates surgical treatment.⁷⁵⁻⁷⁷ Pneumoperitoneum is an indication for surgery. These clinical and radiologic signs clearly indicate that perforation has occurred.

Figure 114-12 Neonatal abdominal mass: mesenteric lymphangioma. **A.** Barium is present in the stomach, duodenum, and small bowel. Gastroesophageal reflux is filling the distal esophagus. The duodenal sweep is displaced to the left. Upwardly displaced, compressed, and opacified bowel loops are seen in the right upper quadrant. **B.** Transverse abdomen sonogram to the right of the midline demonstrates multiple, fluid-filled structures. None of these structures had visible peristalsis because they were portions of the lymphangioma. K, Kidney; S, spine.

Strictures are late findings that develop in about 9% to 35% of children with NEC. About 75% occur in the colon, usually in the region of the splenic flexure; 15% are multiple; and the terminal ileum is involved in 15% of affected infants. They can be manifested after a delay of 20 months, but when they are seen on early studies, they may resolve spontaneously.^{73,78} Children whose NEC-induced bowel perforations are treated with bowel diversion or percutaneous peritoneal drainage have a lower rate of stricture formation than do those who received only medical management. To exclude a stricture, children with NEC may undergo an antegrade contrast study of the entire gastrointestinal tract before feeding is resumed. In infants with diversions, the bypassed bowel should be studied to exclude a stricture before bowel continuity is reestablished.^{73,78} Medical management of infants with suspected NEC includes parenteral nutrition and antibiotic therapy.⁷¹

Most children with NEC, treated medically and surgically, survive. The greatest mortality rate is seen for small premature infants who, too frail to undergo standard laparotomy, are treated with percutaneous peritoneal drainage. Late complications include short gut syndrome, sepsis, abdominal abscess, recurrent NEC, and stricture formation as well as some extra-gastrointestinal problems. NEC survivors constitute the largest group of children with short gut syndrome.

RADIOLOGIC FINDINGS

Abdomen radiograph findings include gastric dilation, a persistently dilated bowel loop, or an unchanging bowel gas pattern.⁷⁹ Pneumatosis intestinalis (Figs. 114-13 and 114-14) is manifested later, and large collections of intramural gas create a linear streaky pattern that parallels the bowel wall or, when seen en face, is manifested as circular lucency around the bowel lumen. Although the bubbly appearance of pneumatosis intestinalis may suggest feces, the premature infant rarely has formed stool within the colon in the first 2 weeks of life.

Figure 114-13 Necrotizing enterocolitis with pneumatosis intestinalis. The bubbly appearance of the abdomen is caused by air within the bowel wall. In some segments, the intramural air clearly parallels the lumen; in other segments, it is seen as a circular pattern surrounding the lumen.

Gas enters the mesenteric veins and subsequently the portal vein and its branches, producing streaky lucencies radiating to the periphery of the liver (see Fig. 114-14). This is an evanescent sign in most children, but to many physicians, it indicates the need for surgery.⁷⁷

Figure 114-14 Necrotizing enterocolitis with portal venous air. Branching lucencies throughout the liver represent gas within the portal venous system (black arrows). Intramural air is also present (white arrows).

Figure 114-15 Necrotizing enterocolitis with perforation: the football sign. A large amount of free peritoneal air outlines the falciform ligament (black arrows). The air has also given the entire right upper quadrant an unusual lucent appearance. The inner and outer walls (white arrows) of multiple bowel loops are visible, another sign of free peritoneal air.

Bowel perforation, the most serious complication of NEC, is manifested by free intraperitoneal air. When the amount of air is large, a diffuse lucency appears over the liver or midabdomen. Air may outline the falciform ligament (Fig. 114-15). The inner and outer surfaces of the bowel wall may be clearly seen. In a few children, air surrounds the umbilical arteries and produces an inverted V sign in the pelvis. Air in Morison's pouch produces a triangular lucency.⁸⁰

Figure 114-16 Colonic stricture from necrotizing enterocolitis. Water-soluble enema depicts an area of minor narrowing in the midtransverse colon (straight arrow) and a more severely narrowed segment at the hepatic flexure (curved arrows).

When free air is suspected, supine abdomen radiographs are supplemented by cross-table lateral radiographs, which are more easily obtained than decubitus or upright radiographs. Free air is visible as lucency anterior to the liver and stomach or as small, triangular lucencies projecting downward from the abdominal wall between the bowel loops.⁸¹

Although ultrasound is not the primary imaging technique for NEC, it can show mural thickening of affected loops and portal venous gas before their detection on radiographs.^{82,83} Intrahepatic portal venous gas is seen as bright reflectors bubbling through the liver. The hepatic parenchyma develops unusually bright echoes in a patchy distribution. Severely affected (gangrenous) bowel loops may demonstrate diminished or absent blood flow when color Doppler imaging is used.⁸³ Focal fluid collections, echogenic free fluid, increased bowel wall echogenicity, and increased bowel wall thickness are also ultrasonographic signs predicting poor outcome.⁸⁴ Early diagnosis of NEC prompts therapy that in most cases aborts the process. When NEC is suspected clinically, the infant is treated accordingly, even in the absence of radiographic findings. If confirmation is required, the neonate can undergo upper gastrointestinal imaging with low-osmolality contrast agents or even contrast enema. A novel approach to confirming NEC employs CT. Urine specimens collected from neonates with NEC who have ingested diluted low-osmolality contrast material have a significantly higher mean CT attenuation value than the urine of normal infants.⁸⁵

Strictures that can develop in the natural history of NEC can cause clinical and radiographic signs of bowel obstruction. Contrast enema (Fig. 114-16) should be used to evaluate the

entire colon and terminal ileum. Although some of the strictures may spontaneously regress, most are resected surgically or dilated with balloon catheters.^{78,86}

Esophageal Atresia

GENERAL CONSIDERATIONS

Esophageal atresia (EA) occurs in about 1 in 5000 live births; boys and girls are equally affected. In more than 80%, the trachea is connected to the distal esophagus by a congenital tracheoesophageal fistula (TEF), but in about 10%, the EA is complete (Fig. 114-17). About 3% to 4% have a proximal fistula (with or without the distal fistula), and about 5% have no atresia but have an aberrant connection between the trachea and esophagus (i.e., H-type fistula).

EA can be diagnosed prenatally but is more often diagnosed at birth, when the infant has difficulty handling secretions, or with the first feeding, when the infant has respiratory distress.⁸⁷ Attempts to pass a nasogastric tube are usually unsuccessful; rarely, the tube may enter the trachea and pass into the TEF and distal esophagus. Prompt diagnosis of EA is necessary to protect the lungs.

The neonate with EA or with EA and TEF must be evaluated for exclusion of other anomalies, including trisomy 21 and the VATER association. The acronym VATER or VACTERL emphasizes that vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb anomalies may occur together.⁸⁸⁻⁹¹ Physical

examination and imaging studies are performed before surgery to find other anomalies that need emergent correction (e.g., duodenal atresia), influence the standard surgical correction of TEF (e.g., right aortic arch), or affect mortality (e.g., renal agenesis, duct-dependent cardiac lesions). In about 50% of infants, EA is an isolated anomaly.

The presence of a distal fistula can be diagnosed clinically (see Fig. 114-17) because the affected neonate has a rounded abdomen and bowel sounds. The infant with EA and no distal fistula has a scaphoid abdomen and absent bowel sounds.

The stable neonate with EA and TEF undergoes surgical correction in the first few days of life. Surgical options include end-to-end or end-to-side anastomosis.^{90,91} Surgery can be performed through traditional thoracotomy or video-assisted thoracotomy.^{92,93} Parenteral nutrition is provided for a few days until postoperative studies confirm that the anastomosis is intact and oral feedings can be given safely.

When there is a large gap between the proximal and distal segments, a common problem in the child with EA and no TEF, primary correction is usually not attempted in the neonatal period. Nutritional needs are met by a gastrostomy tube placed under surgical or radiologic guidance.⁹⁴ The upper pouch is diverted so that secretions within it will not be aspirated. A neoesophagus is later created by interposing a segment of bowel or pulling the stomach into the esophagus, creating an anastomosis between the proximal esophagus and the stomach.⁹⁵⁻⁹⁷ This surgery is often delayed until the child is 1 year old. Nonsurgical anastomosis in EA may be created by magnetic lengthening of the esophageal segments with placement of a magnet in both ends of the upper and lower pouches, using the mouth and gastrostomy for catheter insertion.⁹⁸ Postoperative complications are numerous, regardless of the type of repair performed. An anastomotic leak is seen in 10% to 20% of children who undergo primary repair in the neonatal period (Fig. 114-18). Anastomotic narrowing or stricture formation (Figs. 114-19 and 114-20) occurs in 15% to 30% of cases because of anastomotic leaks with scarring, ischemic change from tension on the anastomosis, or gastroesophageal reflux.⁹⁹⁻¹⁰² A change in caliber at the anastomosis does not always indicate stricture but may instead result from residual dilation of the previously obstructed upper esophageal segment. Distal esophageal narrowing may be caused by congenital esophageal stenosis or gastroesophageal reflux (Fig. 114-21).¹⁰⁰ Bougienage and balloon dilation are used to treat these strictures.¹⁰³

Development of a fistula at the surgical site (Fig. 114-22) or late detection of a proximal pouch fistula (Fig. 114-23) may cause postoperative feeding difficulty simulating aspiration. Children with an H-type fistula (Fig. 114-24) may have only intermittent feeding problems because the fistula may not be patent at all times. The muscle wall of the fistula may contract, or the fistula may be blocked with mucus or food. The H-type fistula can remain undetected for years, until esophagography is performed to evaluate the cause of multiple pneumonias.

Symptomatic gastroesophageal reflux and pulmonary disease are common throughout the lives of children with EA and TEF. Gastroesophageal reflux results from a primary abnormality of the distal esophagus, postsurgical changes in the anatomy of the gastroesophageal junction, poor antegrade peristalsis, or delayed gastric emptying.^{100,101,104} Virtually all children with EA have disordered esophageal motility. If a fundoplication is needed to

Figure 114-17 Types of esophageal atresia. Common forms of esophageal atresia (EA) are depicted.

treat the gastroesophageal reflux, it must be modified so that it does not obstruct the poorly peristaltic esophagus.¹⁰⁵

CT studies done years after repair have documented structural and functional abnormalities of the trachea and puddling of fluid in the dilated upper esophagus.¹⁰⁶ Tracheal

abnormalities may be caused by maldevelopment of the foregut or surgical changes.¹ Respiratory tract symptoms may persist throughout life.^{99,101}

RADIOLOGIC FINDINGS

The prenatal diagnosis of EA without TEF is suggested by the presence of polyhydramnios with absence of fluid in the

Figure 114-18 Anastomotic leak after esophageal atresia and tracheoesophageal fistula repair. As contrast material reaches the anastomosis, it passes into the distal esophagus and into the posteriorly directed leak. Notice the narrowing of the proximal trachea (arrows).

Figure 114-20 Anastomotic stricture after tracheoesophageal fistula repair. A soft tissue density with air-fluid level (arrows) displaces the trachea to the left. This is the dilated upper pouch above a narrowed anastomosis. The child is acutely symptomatic because food is impacted at the anastomosis.

Figure 114-19 Stricture formation after esophageal atresia and tracheoesophageal fistula repair. **A.** A study performed in the early postoperative period demonstrates mild narrowing at the anastomotic site. This can be normal. **B.** Several months later, a study shows a severe stricture causing increased dilation of the proximal esophagus.

Figure 114-21 Gastroesophageal reflux after tracheoesophageal fistula repair. Reflux has produced such severe narrowing of the distal esophagus that a pea (P), swallowed whole, could not pass into the stomach.

stomach.^{87,107} The fluid-filled upper pouch may be detected with ultrasound, with MRI occasionally used for confirmation.

Radiographs

Chest and abdomen radiographs should be scrutinized for vertebral segmentation and limb anomalies as part of the VACTERL association (Fig. 114-25); tetralogy of Fallot and right-sided aortic arch, for avoidance of injury during thoracotomy, which is usually performed on the right; and bowel gas, to differentiate pure EA from EA with TEF and to detect other gut atresias.

Preoperative Contrast Studies

Preoperative identification of a proximal fistula is desired at some institutions and not at others. Evaluation for possible fistula is performed with lateral fluoroscopy of the upper esophagus with the child supported in a semiupright position. A slow, manual injection of a few milliliters of low-osmolality contrast agent through a feeding tube placed in the upper pouch defines the pouch (Fig. 114-26; see also Fig. 114-23). As soon as a fistula is identified, the injection is stopped. When there is no fistula, contrast material is removed through the feeding tube.

In the child with EA and no TEF, barium studies are done through the gastrostomy tube to define the length of the lower esophageal segment before surgery. The lowest extent of the upper pouch is defined by a large-bore catheter. The lower segment may be seen with refluxed contrast material or by means of a tube passed cephalad through the gastrostomy. The

Figure 114-22 Postsurgical esophageal atresia and tracheoesophageal fistula. This fistula is demonstrated several days after surgery. Contrast material instilled into the upper esophagus passes through a fistula (arrowhead) into the trachea. A pleural drain (arrow) is identified.

distal segment tends to extend above the diaphragm for only a small distance (Fig. 114-27).

Because the H-type TEF is not always patent, it may be difficult to demonstrate. The esophagus must be distended, and in some children, a second or third study may be necessary to see the fistula. Repeated barium esophagography may be performed by placing a feeding tube in the upper esophagus and giving a bolus injection of contrast medium manually. The fistula has an N rather than an H shape as it passes superiorly and anteriorly from esophagus to trachea (see Fig. 114-24). Although CT performed in the sagittal plane can demonstrate EA, a distal TEF, and the length of the gap between the upper and lower segments, there has been little application of this technique.

Ultrasound Studies

Sonography is performed to search for kidney malformations included in the VACTERL association: agenesis, ectopia, and fusion anomalies. Associated urethral anomalies are usually detected by clinical inspection.

Postoperative Contrast Studies

About 5 days after surgery, esophagography is performed to detect anastomotic leakage (Fig. 114-28; see also Fig. 114-18). Low-osmolality contrast agent may be used initially, and if the esophagus is intact, the remainder of the study can be performed with barium.

Figure 114-23 Poorly performed preoperative study of the upper pouch: esophageal atresia with proximal and distal fistulas. The upper pouch is overfilled with contrast medium. The trachea is being filled through a tiny fistula (arrows). Contrast material from the trachea is outlining the distal tracheoesophageal fistula and the upper portion of the distal esophageal segment (arrowheads). The upper and lower esophageal segments are closely apposed.

Figure 114-24 H-type tracheoesophageal fistula. The contrast agent injected into the upper esophagus fills the esophagus (E), the fistula (arrow), and the trachea (T).

Figure 114-25 VATER association. A feeding tube is coiled in the upper esophageal pouch (open arrows). Eleven ribs are present on the left and 12 on the right. Segmentation anomalies, including a hemivertebra, are seen at the thoracolumbar level (solid arrow). The right hemithorax is opacified, and the mediastinal contents are shifted to the right because the right lung is agenetic. This child also had unilateral renal agenesis.

Figure 114-26 Esophageal atresia without tracheoesophageal fistula. The upper pouch is filled with a small amount of contrast material. No fistula is identified. This study was performed with the patient in the supine rather than in the preferred upright position.

Figure 114-27 Gastrostomy injection of an esophageal atresia without a tracheoesophageal fistula. A feeding tube is in the upper esophageal pouch (arrow). Contrast material injected into the stomach through a gastrostomy has refluxed into the short distal esophageal segment. The distance between the distal aspect of the upper pouch and the proximal aspect of the distal esophagus is approximately the height of five vertebral bodies.

Figure 114-28 Postoperative study in a child with esophageal atresia and no tracheoesophageal fistula. Contrast material passes through the anastomosis (arrows) between the previously diverted upper esophageal segment and the redundant neoesophagus created from multiple small bowel loops.

When a child's eating pattern deteriorates, barium esophagography should be performed to exclude narrowing at the anastomosis or distal esophagus. Refusal of solid food may be the first sign of narrowing. During this examination, the anastomosis must be challenged with large amounts of contrast material. Small sips poorly distend the esophagus, allowing an abnormal segment to be overlooked. A child who presents with drooling or complete refusal to eat may need a contrast study to detect a foreign body or food impacted above the anastomosis or distal esophagus (see Figs. 114-20 and 114-21).¹⁰⁸

Laryngotracheal Cleft

Laryngotracheal or laryngotracheoesophageal cleft is a rare, severe failure of foregut division that has a slight male predominance. The cleft is of variable length and is frequently associated with EA and TEF.¹⁰⁹ The EA and TEF may mask the laryngotracheal cleft because the symptoms are similar: coughing, inability to handle secretions, and recurrent pneumonias. This anomaly, which causes a toneless cry, is also associated with the anomalies that compose the VACTERL association and with coarctation of the aorta and transposition of the great vessels.¹⁰⁹⁻¹¹¹ Death in the neonatal period is common because of the multiple anomalies.

The diagnosis of laryngotracheal cleft is confirmed with endoscopy. Postoperative radiologic studies should be performed with small amounts of contrast agent given slowly so that any residual cleft can be differentiated from aspiration. Surgery is necessary to divide the trachea from the esophagus. The extent of the cleft and the associated tracheomalacia make reconstruction difficult in many children.

Jejunal and Ileal Stenosis and Atresia

Duodenal atresia is discussed in Chapter 116. Jejunal and ileal atresia occur in about 1 of 5000 births.¹¹² Prenatal ultrasound shows polyhydramnios in about 50% of cases. Atresia may be diagnosed after birth when vomiting and abdominal distention develop.

Jejunal and ileal atresia are thought to result from a vascular insult to the bowel by focal pressure, by compromise of the mesenteric root, by intravascular thrombosis, or by failure of complete recanalization of the bowel.¹¹²⁻¹¹⁷ Multiple levels of atresia are seen in 30% of affected neonates.¹¹²⁻¹¹⁷ Most cases occur sporadically, although hereditary syndromes of multiple gastrointestinal atresias have been described.^{118,119}

Atresias are classified by differences in the discontinuity of the bowel and the mesentery (Fig. 114-29).¹¹⁵ Atresia is about six times more frequent than congenital stenosis.¹¹⁴ About one third of children with jejunoileal atresia have malrotation of the bowel.³

TREATMENT

Improvements in operative technique and postoperative care have significantly enhanced the outcome of patients with small bowel atresia. The choice of operation depends on the site, extent, and type of atresia and the extent of proximal bowel dilation.¹¹²⁻¹¹⁷ Short gut, defined as a residual bowel with less than half of its normal length of 200 cm, has been a consistent

cause of morbidity and mortality. Short gut may initially be compensated for by total parenteral nutrition, but the most severely affected children are candidates for liver transplantation because of complications from total parenteral nutrition hepatitis.

Figure 114-29 Classification of bowel atresia. In type I, there is a web or diaphragm between adjacent bowel loops. In type II, there is a discontinuity of bowel, usually with dilation of the proximal segment. The mesentery is intact. In type IIIa, there is a gap in the mesentery and a discontinuity between the bowel loops. In type IIIb, there is a long segment of atretic small bowel. The remaining small bowel has a corkscrew or apple peel appearance. In type IV, there are multiple areas of intestinal atresia. (From Grosfeld JL, Ballantine TVN, Shoemaker R: *Operative management of intestinal atresia and stenosis based on pathologic findings*. *J Pediatr Surg* 3:368–375, 1979.)

RADIOLOGIC FINDINGS

When prenatal sonography demonstrates polyhydramnios in conjunction with dilated bowel, small bowel atresia should be considered.^{120,121} Prenatal sonography is more successful at detecting duodenal atresia than other intestinal atresias.¹²⁰ MRI can also demonstrate fetal bowel atresia. Postnatal abdomen radiographs demonstrate dilated, air-filled bowel loops proximal to the atretic or stenotic segment. The proximal loop nearest to the obstruction may be dilated out of proportion to the other segments and have a round edge (see Fig. 114-10). No distal bowel gas is observed in atresia, whereas a paucity of distal air is found in stenosis. Peritoneal calcifications indicate that the atresia is complicated by meconium peritonitis (Fig. 114-30; see also Fig. 114-10). However, meconium peritonitis can be present even when no calcifications are seen radiographically or at surgery (Fig. 114-31). Intramural calcifications have been reported in children with intestinal atresia but may also occur without atresia.

Air usually provides adequate contrast for determining the level of obstruction. With jejunal atresia, few loops are filled with air or have air-fluid levels (see Fig. 114-10). When multiple dilated loops are present, the obstruction is more likely to be in the ileum (Fig. 114-32). When there is an extremely low ileal obstruction, the dilated loops may fill the entire abdomen and make differentiation from colonic obstruction impossible.

To exclude a second distal obstruction in the child with suspected jejunal atresia, a contrast enema may be performed. Because of the risk of perforation, low-osmolality contrast agents are preferred for these studies. A normal-caliber colon is present when the obstruction is high because the secretions of the bowel distal to the obstruction are passed into the colon, which preserves its reservoir function. A small-caliber colon implies that there is an obstruction in the distal small bowel and that small bowel contents cannot enter the colon (see Fig. 114-30). Rarely, extrinsic compression can so completely obstruct patent bowel that microcolon can develop.¹²² Ultrasound may be useful when secondary intraperitoneal processes, including

Figure 114-30 Ileal atresia. **A.** Dense calcifications (arrowheads) rim the lateral aspect of the upper abdomen. Notice the dilated bowel loops proximal to a surgically proven high ileal atresia. **B.** Contrast enema in a different patient with ileal atresia shows a small-caliber colon and reflux of contrast material into a meconium-filled terminal ileum (arrows).

Figure 114-31 Meconium peritonitis. **A.** On the chest and abdomen radiograph, there is a paucity of abdominal gas, perhaps because of suction and ventilation through the endotracheal tube. Meconium peritonitis causes generalized abdominal haziness, bulging flanks, and centralization of bowel loops. **B.** The longitudinal sonogram reveals a peritoneal collection of meconium (arrows) anterior to the echogenic neonatal kidney (K). The meconium is less echogenic than the solid structures, but it contains more echoes than simple transudative ascites. H, Cephalic; F, caudal.

Figure 114-32 Colonic atresia. Multiple dilated bowel loops are present. Water-soluble contrast material fills a small-caliber colon. The contrast material did not pass proximal to the hepatic flexure, the site of the atresia.

meconium peritonitis, are suspected. Free fluid, free meconium, or enterocysts may be detected (see Fig. 114-31). Meconium is echogenic because it is a complex substance composed of secretions, desquamated cells, and lanugo hairs.¹²³

If a large amount of bowel is atretic or resected, postoperative barium studies of the small bowel may show many changes that represent the bowel's attempts to compensate for its loss of length.¹²⁴ The small bowel becomes dilated, the folds become thicker than usual, and transit time may be increased.

Meconium Peritonitis

When bowel perforation occurs in utero, sterile meconium leaks into the peritoneal cavity and creates a chemical peritonitis: meconium peritonitis. The perforation is caused by any process that may produce bowel ischemia: volvulus, internal hernia, intussusception, or meconium ileus with or without cystic fibrosis.¹²⁵⁻¹²⁹ The peritonitis is associated with atresia, adhesions, intra-abdominal cystic masses, ascites, scrotal masses, and, in many cases, intraperitoneal or scrotal calcifications (see Figs. 114-10 and 114-30).¹²⁵⁻¹³¹ Meconium peritonitis occurs in 1 of 35,000 live births.

Meconium peritonitis sometimes has been categorized as several distinct forms: fibroadhesive, cystic, and generalized. Fibroadhesive meconium peritonitis is defined by dense bands and membranes that form around and across bowel loops in response to the peritoneal process. Cystic meconium peritonitis develops when the perforation is contained by inflammatory tissue and adjacent loops of bowel that are matted together. After birth, the "cyst" may be filled with fluid if the perforation

has sealed or with air and bowel contents if the cavity remains in continuity with the bowel lumen. In the generalized form of meconium peritonitis, loosely adherent or free-floating plaques of calcium are scattered throughout the peritoneal cavity. The calcifications may not be visible on abdominal radiographs.

CLINICAL FINDINGS

Many children with meconium peritonitis are diagnosed prenatally.¹²⁸⁻¹³⁰ Most of those diagnosed postnatally present within the first 24 hours of life with abdominal distention and bilious vomiting resulting from adhesive bands, small bowel atresia, or meconium ascites (see Figs. 114-10, 114-30, and 114-31). Asymptomatic children may not be diagnosed until abdomen radiographs obtained for other reasons demonstrate peritoneal calcification.

Meconium peritonitis and cystic fibrosis may occur independently, and calcification of meconium most often occurs in the absence of cystic fibrosis.¹³¹ The differential diagnosis of abdominal calcifications in a neonate is limited: tumors (e.g., neuroblastoma, hepatoblastoma, teratoma), calcification in the walls or lumen of a bowel loop, and retroperitoneal calcifications from prenatal adrenal hemorrhage or renal vein thrombosis. Although all children with meconium peritonitis should undergo a sweat chloride and stool trypsin and chymotrypsin tests to exclude cystic fibrosis, less than 10% of patients have the disease.¹³⁰ The prognosis for those with meconium peritonitis is good, with a survival rate of about 90%.¹²⁸⁻¹³⁰

RADIOLOGIC FINDINGS

The sonographic criteria for meconium peritonitis include fetal ascites that may have echogenic debris, echogenicity along the peritoneal surfaces, abnormal cystic abdominal masses, and bowel dilation.^{129,130} Ascites alone may be a sign of meconium peritonitis; in utero, this may simulate fetal hydrops. Abdominal radiographs may show peritoneal calcifications (see Figs. 114-10 and 114-30), intestinal obstruction, mass effect, and, uncommonly, pneumoperitoneum.

Sonography should be used if there is ascites or a palpable mass in the pelvis or abdomen because it can define the size of the mass and exclude other masses or obstructive lesions. Sonography can differentiate the usual ascites from meconium peritonitis with “dirty” ascites (see Fig. 114-31). Radiographs of the skeleton may show metaphyseal dense bands, which are thought to develop at the time of the perforation.¹³²

Colonic Atresia

GENERAL CONSIDERATIONS

The incidence of atresia is lower in the colon than elsewhere in the gut; it occurs in about 1 of 40,000 live births.¹¹⁵ The transverse colon is more frequently involved than other sites, and there is a slight female predominance.¹³³ In contrast to the increased rate of prematurity found with other intestinal atresias, children with colonic atresia are more likely to be born at term. The neonate with colonic atresia presents with vomiting and abdominal distention. Meconium might have passed normally.

The differential diagnosis of colonic atresia includes other causes of low obstruction: Hirschsprung’s disease, duplication,

meconium plug, intussusception, and distal ileal processes. A contrast enema should be performed to narrow the diagnostic possibilities and to direct additional testing and therapy.

RADIOLOGIC FINDINGS

As with other intestinal atresias, prenatal sonography of colon atresia frequently demonstrates polyhydramnios and dilated, fluid-filled bowel loop. Postnatal abdomen radiographs indicate a low obstruction, and the dilated bowel loops may have air-fluid levels or a bubbly appearance because of intraluminal meconium. The radiographic diagnosis of colonic atresia is difficult, particularly in the first few hours of life because air may not have reached the most distal bowel segment.

Sonography is useful for excluding the presence of ascites or mass lesion. A contrast enema with a low-osmolality contrast agent is the diagnostic study of choice. The examination should be performed with great caution because of an increased incidence of colonic rupture in patients with atresia. The contrast column ends abruptly and may taper or have a round, “cobra head” or club deformity if a membrane is present (Fig. 114-32).¹³⁴ The colon may be normal or small in caliber, depending on when luminal occlusion occurred. If a transition zone is observed, Hirschsprung’s disease also may be present.¹³⁵

Imperforate Anus

CLINICAL FINDINGS

Imperforate anus is a complex anomaly that occurs in about 1 of 5000 live births, with a slight male predominance.¹³⁶⁻¹⁴⁰ The spectrum of anorectal malformations is broad and varies with the patient’s sex (Fig. 114-33). Numerous classifications of the variants of imperforate anus have been made; one widely used system is the Wingspread classification.¹³⁶ Others with a strong basis on clinical inspection performed at age 1 day have been developed.^{137,138} Boys are more likely than girls to have enterourinary fistulas because they lack interposed genital structures (Fig. 114-34). Girls have a high incidence of enterovaginal fistulas and cloacal anomalies.

The distal extent of the rectum must be delineated because it determines whether the infant needs neonatal colostomy and the probability that other malformations are present.¹³⁷⁻¹⁴² The position of the distal rectal pouch in relation to the levator ani muscles is used to categorize grossly the different types of imperforate anus. When the rectum ends above the levator ani muscles, the infant has a high or supralevator imperforate anus. When the rectum ends below these muscles, the infant has a low or infralevator imperforate anus. Radiologic and clinical data are used to differentiate high from low lesions. Abdomen radiographs, ultrasound, CT, and MRI may have roles in this process.

A low lesion is suggested when there is a fistula, perineal pearls, corrugated appearance of the extrinsic sphincter, or normal-appearing female urethra and vagina. The presence of meconium on the perineum or in the urine suggests a low lesion.^{137,139} Infants with low lesions undergo anoplasty or temporary enlargement of the fistula. High lesions should be suspected when there is no fistula, when there is a smooth perineum, or when a girl has a single perineal orifice (i.e., cloacal anomaly). Neonates with high lesions undergo a colostomy. A corrective pull-through procedure is performed when the child is about 1 year old.

Figure 114-33 Classification of imperforate anus. This diagram shows many of the possible relationships of the imperforate anus to the internal organs in children of both sexes. (Modified from Grosfeld JL, Ballantine TVN, Shoemaker R: *Operative management of intestinal atresia and stenosis based on pathologic findings*. *J Pediatr Surg* 3:368–375, 1979.)

Genitourinary abnormalities are common in infants with imperforate anus.¹⁴⁰⁻¹⁴² Renal anomalies (e.g., absence, agenesis, ectopia, horseshoe kidney) are more common and more severe in children with high imperforate anus. A fistulous connection to the urinary tract, usually to the urethra or the bladder, is present in about 23% of children with supralelevator imperforate anus. The fistula may be diagnosed at birth when there is air in the bladder on early postnatal plain abdomen radiographs or meconium in the urine. Otherwise, the fistula is sought with voiding cystourethrography in the neonatal period or pressure antegrade colography before colostomy closure.¹⁴³ In children with the VACTERL association, there is an increased incidence of congenital urethral lesions: duplications, stricture, and megalourethra.¹⁴⁰

The incidence of cardiovascular malformations, especially tetralogy of Fallot and ventricular septal defect, is increased in children with otherwise isolated imperforate anus. The cardiac anomalies contribute significantly to the mortality rate of children with imperforate anus. Tethered spinal cord may occur

with or without vertebral anomalies in up to 20% of children with imperforate anus.¹⁴⁴

TREATMENT

The corrective procedure depends on the anatomy of the congenital lesion and surgical preference. Most procedures for high imperforate anus are variants of the posterior sagittal anorectoplasty.^{145,146} The goal of surgery is to preserve and, if necessary, to enhance the mechanisms of continence. Urinary tract anomalies that need correction are repaired at the time of imperforate anus surgery.

The incidence of spinal deformity and intraspinal lesions is lower in children with low imperforate anus than in those with high imperforate anus. These children also tend to have better development of the levator sling, a more intact neural arc, and more normal evacuation patterns after surgery than children with high imperforate anus. After the corrective surgery, girls have greater success at achieving continence than boys do.^{140,145}

Figure 114-34 Rectourethral fistula. A catheter placed in the urethra for voiding cystourethrography passed into the rectourethral fistula. Contrast material outlines the distal rectal segment.

This difference probably reflects the fact that more than 90% of boys but only 69% of affected girls have supralelevator imperforate anus.

RADIOLOGIC FINDINGS

Prenatal Ultrasound

Prenatal ultrasound may suggest bowel obstruction in patients with imperforate anus; however, dilated bowel is seen only in the later stages of gestation. Intraluminal enteroliths may be seen in fetuses with imperforate anus. Because infants with jejunal and ileal atresia have few extragastrointestinal abnormalities, detection of any of the stigmata of the VACTERL association in a fetus with multiple dilated bowel loops suggests imperforate anus.

Radiographs

A number of associated anomalies of imperforate anus can be visualized on radiographs of the chest and abdomen: spinal deformity with absent, additional, or fused segments; scimitar sacrum; tetralogy of Fallot; and ventricular septal defect. The bowel gas pattern may show little except changes of distal obstruction. The intraluminal calcification reported in a small number of infants with imperforate anus may be caused by prenatal mixture of urine and colon contents, although it can occur in the absence of obstruction or fistulous communication between the gut and the genitourinary tract (Fig. 114-35; see also Fig. 114-34).

When the physical examination does not provide enough information about the level of the distal pouch, it must be defined radiographically. A lateral radiograph of the rectum obtained with the infant inverted (i.e., invertogram) was once the standard way to assess rectal position.¹⁴⁶ The level of the

Figure 114-35 Imperforate anus with rectourethral fistula. A rectourethral fistula is demonstrated on this voiding cystourethrogram. As the child voids and fills the urethra, contrast material passes through the fistula (arrow) into the blind-ending rectum. The fistula is demonstrated best on lateral radiographs.

levator sling was considered to be the same as the pubococcygeal line: a line drawn from the junction of the superior third of the pubis with the middle third to the inferior aspect of the fifth sacral vertebra. If the rectal air stopped proximal to this line, the imperforate anus was considered to be high, but if it stopped below, it was considered to be low. The invertogram is now not used, and a prone cross-table lateral radiograph of the rectum is obtained with the infant's knees tucked beneath (Fig. 114-36).^{147,148} The prone or knee-chest position is physiologically better for the infant than the invertogram; it also encourages colonic gas to pass to the rectum and tends to prevent distal air from escaping through a fistula. The landmarks used are the same as on the standard invertogram. The radiograph is more accurate when it is obtained after the first 24 hours of life because the delay allows gas to be driven to the most distal portion of bowel.^{147,148}

The CT invertogram (obtained with the child prone or in the knee-chest position) provides better delineation of the anatomy than do abdomen radiographs, but it is not commonly used.¹⁴⁹ On sagittal reconstruction, the distal colon can be seen in relation to the midline bone structures even if it has not yet been filled with air. Percutaneous injection of contrast material through the rectal dimple in an attempt to find a poorly seen distal pouch is rarely performed.

Ultrasound Studies

Sonography can identify the distal rectal pouch because it contains echogenic meconium and can therefore define the anomaly

Figure 114-36 Jackknife position invertogram demonstrating an imperforate anus. The child is positioned prone with the hips elevated on a cloth roll. Barium paste marks the anus. Meconium (arrowheads) in the rectal pouch is outlined by air.

Figure 114-37 Imperforate anus. On a longitudinal sonogram of the rectal pouch in an infant with imperforate anus, the echogenic meconium distends and defines the distal rectal (R) pouch. The pouch-to-perineum distance (P-P) is only a few millimeters. F, inferior; H, superior.

as a high or low lesion (Fig. 114-37).¹⁵⁰ When the pouch cannot be easily classified, it is usually a high imperforate anus. Transperineal sonography has also been used to assess the distal pouch and the puborectalis muscle around it.¹⁵¹ Renal sonography should be routine, and spinal ultrasound is performed even when abdomen radiographs do not demonstrate a spinal anomaly.

Figure 114-38 Imperforate anus: postoperative CT. For the postoperative evaluation of the sphincter muscle in an infant with imperforate anus, pelvic CT shows that the sphincter muscles (arrows) are extremely thin and underdeveloped.

Gastrointestinal and Genitourinary Contrast Studies

Voiding cystourethrography is routinely performed to exclude vesicoureteral reflux, which occurs in almost 50% of children with high imperforate anus and in 35% of children with low imperforate anus. In boys, voiding cystourethrography is also necessary to exclude rectourinary fistula, which requires ligation at the time of pull-through surgery.

Because the fistula may not always fill on the initial examination, pressure-augmented antegrade colography or repeated voiding cystourethrography precedes corrective surgery if the result of the neonatal study was normal.¹⁴³ Water-soluble contrast agents, rather than barium, should be used to fill this unused segment to avoid barium in the urinary tract. The fistula is best seen when the distal colon segment is distended and the infant is in the lateral position (see Fig. 114-35).

Computed Tomography and Magnetic Resonance Imaging

Preoperative evaluation of the levator sling can be performed with CT or MRI, but it is not routine.^{149,150} MRI displays the sphincteric muscle complex better than CT, which is limited by the small amount of fat present in the neonate. MRI also can better demonstrate the muscles best imaged in the coronal or sagittal planes. When there is insufficient intrinsic muscle to produce continence, surgical results may be disappointing unless special procedures to buttress the muscles are also performed.¹⁵²

MRI is useful in evaluating the spinal cord when an abnormality is detected on ultrasonography.¹⁵³⁻¹⁵⁵ In the neonatal period, MRI also displays the distal portion of the colon well; the impacted meconium produces an intense signal.

Postoperative Studies

Postoperative studies are performed when there is clinical suspicion of an anastomotic leak. Later contrast studies are performed if there is fecal soiling or severe constipation. CT and MRI are occasionally used to assess the position of the colon pull-through in relation to the sphincteric muscle complex (Figs. 114-38 and 114-39).¹⁵⁶ The rectum should be centrally

Figure 114-39 Imperforate anus: MRI of pull-through. Axial MRI shows the anal pull-through in a good position. The rectum (R) is centrally placed within a well-developed sphincteric muscle complex.

positioned within the sphincteric muscle complex to ensure proper function. Poor centralization of the neorectum is more common in children with a poorly developed sphincteric muscle complex than in those with normally developed muscles (Fig. 114-38). A child who evacuates well initially but later develops incontinence should be evaluated for a spinal cord lesion that produces tethering.¹⁵³⁻¹⁵⁵ A child who has difficulty beginning at the time of surgery should be evaluated for Hirschsprung's disease, a disorder that occurs with increased frequency in patients with imperforate anus. In some children, especially those prone to constipation, fecal continence is achieved by percutaneous cecostomy and antegrade enema.¹⁵⁷

Imperforate Anus Variants

CLOACAL MALFORMATION

In girls, a variant of imperforate anus associated with more profound renal, vaginal, and uterine abnormalities is the cloacal malformation.^{136,158-160} It occurs in 1 of 40,000 to 50,000 births. This anomaly can be diagnosed at birth when a "bland" or "featureless" perineum with only one opening is detected. This opening is usually beneath an enlarged clitoris. The external anatomy indicates that at some level, the bladder, urethra, vagina, and rectum merge into a common distal channel of variable length. The numerous possible configurations depend on which distal channel is dominant.

In one third of neonates with cloaca, the vaginal opening of the confluent channel is stenotic, which causes hydrocolpos with resultant abdominal mass.¹⁶⁰⁻¹⁶² Urinary sepsis may develop if the bladder cannot drain freely or if there is associated reflux. Management in the neonatal period requires that urinary tract abnormalities be corrected and that the fecal stream be diverted.

Genitourinary tract anomalies, such as solitary kidney, renal ectopia, ureteral obstruction, vesicoureteral reflux, and bladder diverticula, are common. Failure of the fusion of müllerian structures is frequent and results in duplication of the vagina, a vaginal septum, and uterine duplication. Cardiac, skeletal, and other gastrointestinal anomalies are also seen with increased frequency.

TREATMENT

Corrective surgery is frequently delayed until after 1 year of age.^{159,160} Although in some girls the anatomy lends itself to a one-stage correction, those with a long common channel need a staged repair for creation of a urethra, a separate vagina, and a functioning anus. The goal of surgery is to achieve fecal and urinary continence and normal sexual function.

RADIOLOGIC FINDINGS

To prevent injury or deterioration of the urinary tract, the internal anatomy must be accurately delineated in the neonatal period. An abdomen radiograph can document the presence or absence of vertebral deformity, abdominal calcifications, or a large pelvic mass (i.e., dilated vagina).

Water-soluble contrast studies are needed to visualize the length of the common channel and the relationships of each of the systems above it. These studies are performed with catheters introduced through and occluding the perineal opening while the contrast agent is being injected; the catheter is introduced from above if colostomy, vesicostomy, or vaginostomy is present.^{161,162} Any accessory openings should also be injected with contrast material.

Ultrasound is useful for detecting renal, uterine, or vaginal abnormalities. However, the common channel is difficult to visualize with ultrasound or CT.^{161,162} Three-dimensional magnetic resonance genitography with instillation of gadolinium solution into the common channel, vesicostomy, and distal colon by augmented pressure delineates the complex anatomy.¹⁶³ MRI is helpful in evaluating the spinal cord; tethering of the cord is common, and this affects later bowel and bladder function.

Caudal Regression

Caudal regression is a rare association of severe malformations of the lower spine, lower limbs, genitourinary tract, and anorectum that occurs in about 1% of the offspring of diabetic mothers.^{164,165} The infant with fusion of the lower limbs into a single structure is said to have a specific form of caudal regression: sirenomelia, or mermaid deformity.¹⁶⁶ This is usually a lethal variant associated with complete renal agenesis. Other children with milder changes of caudal regression present with many of the classic stigmata of the VACTERL association. The lower limbs may be atrophied, malrotated, or contracted. The genitourinary anomalies are the same as those seen in imperforate anus, and the degree of bladder dysfunction reflects but does not parallel the spinal deformity.

Many of the changes can be diagnosed prenatally.¹⁶⁷ The spinal and limb changes are usually apparent earlier than the anorectal anomaly. Spinal anomalies are usually evaluated by MRI.¹⁶⁸

Currarino Triad

Another variant of anorectal malformations is the Currarino triad, which additionally includes a sacral deformity and presacral mass.¹⁶⁹⁻¹⁷¹ The anorectal lesion has been described as being anal stenosis, anal ectopia, imperforate anus, or Hirschsprung's disease.¹⁷² Sacral lesions are not uncommon in children with anorectal malformations, but presacral masses (e.g., anterior

Figure 114-40 Currarino triad.

A. Anteroposterior radiograph of the pelvis shows a large amount of feces obscuring visualization of the sacrum. The sacrum is abnormally formed and is scimitar shaped (arrows). **B.** Lateral radiograph from a barium enema shows that the rectal channel is effaced by a posterior extrinsic mass. The proximal colon is dilated. **C.** Axial CT scan demonstrates a water density anterior sacral meningocele (M) compressing and displacing the bladder (B) and the colon (C).

meningocele, duplication, teratoma) are. In some children, the presacral mass is detected years after the anal lesion has been repaired (Fig. 114-40).

In about 50% of cases, the triad is inherited in an autosomal dominant manner.^{168,170} As in other variants of imperforate anus, ultrasound evaluation of the spinal cord followed by MRI when the ultrasound finding is abnormal is an important part of patient evaluation because tethering of the cord is common in this entity.¹⁷³

Other Low Obstructive Lesions

Many low obstructive lesions are functional rather than mechanical. When a contrast enema is performed in a child with signs of Hirschsprung's disease, the diseases described in the following sections should be considered. Any process that causes ileus may simulate obstruction and should be excluded clinically.

MECONIUM ILEUS

Clinical Findings

Meconium ileus indicates cystic fibrosis in more than 80% of patients.¹²⁵ The narrowed lumen of the distal ileum is impacted with meconium pellets, and the dilated segment above contains thick meconium. The neonate does not pass meconium or stool.¹²⁵ The first-year mortality rate for affected infants has

diminished markedly but remains about 10%. Further discussion of meconium ileus is included in Chapter 118.

Therapy

Cleansing enemas of hypertonic, water-soluble contrast agents have long been used to diagnose and to treat this disorder.¹⁷⁴ Because fluid drawn into the bowel lumen from the intravascular space may produce dehydration, the neonate should have an intravenous line in place. The necessity of refluxing contrast material into the obstructed terminal ileum may result in perforation of the unused microcolon; most children with perforation do well, despite the need for immediate surgery.¹⁷⁵

Radiologic Findings

Abdomen radiographs show multiple, dilated small bowel loops (Fig. 114-41). A granular appearance of the right lower quadrant and the absence of air-fluid levels in this region result from the abnormally thick intraluminal meconium, which does not change position with gravity.

Contrast enema demonstrates a small-caliber colon that is malrotated in 33% to 50% of patients.¹²⁵⁻¹²⁷ Contrast material refluxed into the terminal ileum outlines the impacted meconium (see Fig. 114-41). To avoid perforation, the physician should not attempt to fill the entire obstructed segment with the first contrast enema. When some of the terminal ileum is filled, the study is concluded. The infant is returned to the nursery and observed clinically. If there is continued

Figure 114-41 Meconium ileus. **A.** Air-filled, dilated bowel loops are present throughout the abdomen. Multiple loops of meconium-filled gut are seen above the distal meconium impaction. **B.** The caliber of the colon is slightly diminished on contrast enema. As contrast material refluxes into the dilated and obstructed terminal ileum (I), it is diluted by the intraluminal meconium.

Figure 114-42 Ultrasound appearance of meconium ileus. **A.** Round loops of bowel (arrows) full of echogenic meconium are visualized on this transverse scan. **B.** Echogenic meconium (M) fills the dilated bowel loop (arrow).

obstruction, additional enemas are given, usually 1 day apart. Each time, it is necessary to observe that the retrograde flow reaches the impacted meconium and ultimately enters the dilated bowel loops above.

Prenatal or postnatal sonography can show the inspissated meconium or meconium in the dilated proximal bowel loops (Fig. 114-42).^{120,121} Prenatal diagnosis of meconium ileus is increasingly common.

MECONIUM PLUG SYNDROME

Delayed passage of meconium and abdominal distention are the presenting findings in neonates with meconium plug syndrome, also called small left colon syndrome or functional immaturity of the colon, which occurs in about 1 of 500 to 1000 neonates. Of these, up to 25% have cystic fibrosis, and another 5% to 13%

have Hirschsprung's disease.¹⁷⁶⁻¹⁸² Other factors associated with meconium plug include prematurity, maternal diabetes, and maternal treatment with magnesium sulfate.^{179,181,182} In most children, meconium plug is an isolated process without a specific cause.

Most children are promptly and completely relieved by contrast enema, which stimulates passage of the plug. If the obstruction recurs, it is necessary to exclude Hirschsprung's disease by rectal biopsy and to evaluate the patient for cystic fibrosis. When obstructive symptoms develop after an uneventful perinatal period, a contrast enema may be done to exclude Hirschsprung's disease. If it shows filling defects in the terminal ileum, milk curd syndrome should be considered. This also can be treated with a hypertonic contrast enema.¹⁸³ Boys are affected with milk curd syndrome about five times more often than girls are.

Figure 114-43 Meconium plug in Hirschsprung's disease. **A.** Multiple dilated bowel loops fill the abdomen. None can be specifically identified as the colon. The umbilical clamp projects (black arrows) over the lower abdomen. An enema tip is in place (white arrow). **B.** An intraluminal tubular defect (arrows) extends from the descending colon to the rectum. There is a subtle change in the caliber of the colon, with the sigmoid colon being larger than the rectum.

Figure 114-44 Small left colon syndrome. The rectum is large, but the descending colon and sigmoid colon are much smaller than normal. There is an abrupt change in caliber at the level of the splenic flexure, a classic finding.

Radiologic Findings

In children with the meconium plug syndrome, abdomen radiographs demonstrate multiple, dilated bowel loops (Fig. 114-43A).^{177,180} Contrast enema, performed with a water-soluble agent, outlines the adherent plug, which fills the lumen (Fig. 114-43B). The colon may be normal in caliber or have a diminished caliber up to the splenic flexure (Fig. 114-44), as seen in neonates with small left colon syndrome.¹⁸¹

MEGACYSTIS–MICROCOLON–INTESTINAL HYPOPERISTALSIS SYNDROME

The pathophysiologic mechanism of megacystis–microcolon–intestinal hypoperistalsis (MMIH) syndrome has been investigated by many but remains poorly understood.¹⁸³⁻¹⁸⁶ Abnormalities of autonomic inhibitory input to the smooth muscle cells of the small intestine, imbalance of gut peptides, and fibrosis after inflammation have been postulated.

Clinical Findings

MMIH syndrome is a rare condition that occurs almost exclusively in girls.¹⁸⁶ Most cases are sporadic, but in some, there has been a pattern of autosomal recessive inheritance. The clinical presentation may overlap with the chronic intestinal pseudo-obstruction syndrome, which has similar problems of the gastrointestinal tract but variable urinary tract involvement.¹⁸⁷

The affected infant presents shortly after birth with abdominal distention and vomiting. The wrinkled appearance of the abdomen, similar to that of the prune-belly syndrome, may not be appreciated until the huge bladder is catheterized and drained.

Virtually all children with MMIH syndrome die in infancy. Neither pharmacologic stimulation nor ileostomy or colostomy improves gastrointestinal tract function. Hyperalimentation improves nutritional status, but it is a temporizing measure because bowel function is never corrected.

The main alternative diagnosis to MMIH syndrome is Hirschsprung's disease, which is not usually associated with microcolon or a large bladder. In some children, biopsy of the colon may be necessary to exclude the diagnosis.

Radiologic Findings

The MMIH syndrome can be suggested in utero by finding a markedly dilated bladder and upper urinary tract in a female infant.^{188,189} It can be differentiated from other syndromes with bladder distention and upper urinary tract changes because it is not associated with a decreased amount of amniotic fluid.

Male infants with a distended bladder and upper tract abnormalities are more likely to have posterior urethral valves or prune-belly syndrome.

Postnatal radiologic studies may show the dilated upper urinary tract but fail to disclose any site of mechanical obstruction. A contrast enema easily fills the microcolon, which in infants with MMIH syndrome has a tendency to be abnormally rotated or fixed. Contrast studies of the genitourinary tract are

routinely performed to exclude vesicoureteral reflux, a common neonatal cause of dilation. Sonography can show the dilated bladder mass.¹⁹⁰

HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease typically is manifested in the neonatal period. This disorder is discussed in Chapter 118.

CHAPTER OUTLINE

Congenital Anomalies of the Esophagus

Overview

Swallowing Disorders

Vascular Rings

Acquired Abnormalities of the Esophagus

Gastroesophageal Reflux Disease

Eosinophilic Esophagitis

Achalasia

Esophageal Varices

Foreign Body and Caustic Ingestion

Other Esophageal Injuries

Congenital Anomalies of the Esophagus**OVERVIEW**

Many congenital lesions affect esophageal morphology and function. Duplications may be asymptomatic or may be manifested with respiratory or swallowing problems. Esophageal atresia is a complex anomaly, frequently accompanied by anomalies of other organ systems. These disorders are described in Chapter 113.

Some congenital bronchopulmonary foregut malformations, such as agenesis and congenital stenosis of the trachea, are rare and may be associated with esophageal atresia (Fig. 115-1).¹⁻⁷ Also included in the spectrum of bronchopulmonary foregut malformations is esophageal bronchus, characterized by communication between an isolated portion of lung and the esophagus (Fig. 115-2).⁸

Webs and diverticula are also uncommon and may be manifested in childhood with mucosal inflammation and dysphagia (Fig. 115-3).^{6,7} Esophageal diverticulum may be an isolated finding or a manifestation of Ehlers-Danlos syndrome.⁹ In neonates, a posteriorly directed diverticulum should be differentiated from a cavity produced by traumatic passage of a nasogastric or endotracheal tube.¹⁰

Ectopic gastric or respiratory epithelium and tracheal cartilage in the esophagus are associated with focal narrowing and dysphagia.^{2,5,11} Although the incidence of ectopic gastric mucosa in the upper esophagus approaches 21% in pediatric autopsy series, these cases are rare clinically.¹¹

Intramural leiomyomas in children may be familial, syndromic, or isolated.¹²⁻¹⁵ They may produce luminal esophageal narrowing and may be difficult to differentiate from other masses of the middle mediastinum by imaging (Fig. 115-4). Leiomyoblastomas may arise in the esophageal wall in association with other pathologic anomalies, such as pulmonary chondromas.¹³

SWALLOWING DISORDERS

Derangement of the oral portion of swallowing may be due to congenital anomalies, such as absence of the tongue, macroglossia, cleft palate, and micrognathia.^{16,17} Acquired swallowing problems often result from neurologic disorders, such as cerebral palsy, cranial trauma, meningomyelocele, or central nervous system tumors.¹⁶⁻¹⁹

All stages of the swallowing process (oral, pharyngeal, and esophageal) should be observed as part of a real-time, video-fluoroscopic swallowing examination, which is an excellent method for assessing oropharyngeal swallow biomechanics and can be performed with minimal radiation dose.^{16,20,21} Older children are given age-appropriate foods to assess completeness of mastication and the ability to centralize the food within the oral cavity. Some children swallow liquids and puréed foods well but have difficulty swallowing solids. The modified barium swallow is performed with the child in a supported semiupright position, simulating the way the child usually eats. Maneuvers to augment swallowing (e.g., stroking the cheek, additional chin and head support) are more easily performed in this position as well.

Neuromuscular disorders can affect multiple anatomic locations that disrupt the normal swallowing process. Organs that may be impaired include the tongue, which causes poor bolus formation; the palate, which causes nasopharyngeal reflux (Fig. 115-5A); the epiglottis, which causes tracheal penetration or aspiration; the pharynx, which causes poor emptying and premature laryngeal “spillage”; and the cricopharyngeal muscle, which causes obstruction of the passage of the bolus. Failure of cricopharyngeal muscle relaxation is called cricopharyngeal spasm or cricopharyngeal bar and occurs transiently in some normal children (Fig. 115-5B).

Swallowing studies should be performed in conjunction with a speech or occupational therapist who can determine the optimal food volume and feeding implements and may perform compensatory maneuvers that assist swallowing. The examination should be recorded on videotape or digital medium to allow subsequent review.

VASCULAR RINGS*Clinical Findings*

Vascular rings occur when the esophagus and trachea are encircled, displaced, or compressed by the aorta, its branches, or remnants of the fetal circulation.²²⁻²⁴ Some rings are incomplete, but others, such as the double aortic arch, completely surround and frequently compress the esophagus and trachea (Fig. 115-6).

Asymptomatic rings are often incidentally discovered on chest radiographs. In childhood, vascular rings commonly are manifested with stridor during feeding because transient esophageal dilation produces additional tracheal compression;

adults instead tend to have dysphagia as a presenting symptom. Reflex apnea is another presentation and may prompt urgent surgery. Twenty percent of these children also have congenital heart disease.²⁵

The double aortic arch, the most common vascular ring, is usually formed by the larger and more cephalad right aortic arch and the smaller and more caudad left aortic arch. The second most common ring occurs if an aberrant right subclavian artery arises as the last rather than the first branch of a left aortic arch. To reach its normal position, this vessel must pass

from left to right in an oblique, cephalad direction, indenting the posterior aspect of the esophagus. If the left subclavian artery arises as the last branch of a right aortic arch, it produces more tracheal and esophageal impingement because the subclavian originates from the usually small but space-occupying diverticulum of Kommerell, and the normal left-sided ligamentum arteriosum persists.

The right innominate artery, the first vessel to arise from the aorta, originates completely or partially to the left of midline in most children.²⁶ As it crosses from left to right, it may indent the anterior aspect of the trachea. Because many children with this finding are asymptomatic and many symptomatic children outgrow the symptoms, the aberrant right innominate artery is often considered to be a normal variant.²⁶ Severely symptomatic children may respond to innominopecty, a surgical procedure that elevates and fixes the artery away from the trachea.

A vascular sling is an anomaly of the pulmonary artery in which the left pulmonary artery arises in an aberrant fashion from the right pulmonary artery, rather than normally from the main pulmonary artery. The anomalous left pulmonary artery courses from the right to the left in the space between the trachea and esophagus. Children with pulmonary sling have an increased incidence of intracardiac and bronchial anomalies, including ventricular septal defects and variations in the normal branching pattern.

Imaging Findings

Plain radiographs can often suggest the diagnosis of a vascular ring. On the frontal view of the airway or chest, the position of the aortic arch and trachea should always be carefully evaluated (Figs. 115-7 and 115-8). The presence of a right aortic arch in a child with respiratory symptoms suggests that there may be a double aortic arch or right aortic arch with an aberrant left subclavian artery.²² A lateral chest radiograph showing anterior displacement of the trachea suggests the presence of a vascular ring.

Although it is less frequently performed than in the past, barium esophagography often remains the initial imaging study

Figure 115-1 Tracheal agenesis. Despite apparent aeration and development of both lungs, this child had marked respiratory distress. Endoscopy performed after several unsuccessful attempts at intubation revealed tracheal agenesis. The intraoperative study shows that both main bronchi contain barium because they arise from the esophagus.

Figure 115-2 Esophageal origin of right main stem bronchus. **A.** The mediastinum is shifted to the opacified right hemithorax. An air collection in the midline over the lower third of the thorax (arrows) corresponds to the right main bronchus. **B.** The bronchus to the right lung originates and fills with contrast material from the esophagus.

Figure 115-3 Esophageal webs. **A.** On the lateral projection, a small air collection in the prevertebral space (arrow) represents dilated esophagus. **B.** Esophagram shows discrete and partially obstructed esophageal segments separated by multiple webs.

in patients with symptomatic vascular rings. Therefore, radiologists must be able to recognize the characteristic impression that each type of ring produces on the upper esophagus, especially on the lateral view (Figs. 115-9 and 115-10).²²

Even after a vascular ring has been detected by plain radiography or esophagography, advanced cross-sectional imaging is recommended for more detailed evaluation. Magnetic resonance (MR) angiography with and without intravenous administration of contrast material and contrast-enhanced multidetector computed tomography (CT) angiography allow production of high-resolution multiplanar reformatted images and three-dimensional reconstructions that assist in detailing

the complex anatomic relationships between aortic arch structures, trachea, and esophagus (Figs. 115-11 and 115-12). CT and MR angiography are particularly useful for presurgical planning and postoperative and postendovascular evaluation and have largely supplanted conventional catheter angiography for direct visualization of vascular anatomy.^{23,24,27,28} State-of-the-art MR angiography is usually preferred to CT angiography in pediatric patients because it does not require radiation or iodinated contrast material and can provide hemodynamic information. Multidetector CT angiography can be performed when MR angiography is not available, is contraindicated, or is likely to be nondiagnostic.²⁷

Figure 115-5 Abnormal swallowing.

A. Nasopharyngeal reflux. As barium passes over the tongue (T), the palate (P) does not close off the nasopharynx, which fills with barium. **B.** Cricopharyngeal spasm. There is narrowing of the esophagus at the C5 level at the upper esophageal sphincter, which is the cricopharyngeal muscle (arrows).

Figure 115-7 Right aortic arch. The right aortic arch (arrow) indents and displaces the trachea to the left. Normal left-sided aortic knob is absent.

Figure 115-8 Double aortic arch. The larger and higher right arch (curved arrow) indents and displaces the trachea toward the left. Impression from the smaller and lower left aortic arch (straight arrow) is seen along the left margin of the trachea.

Acquired Abnormalities of the Esophagus

GASTROESOPHAGEAL REFLUX DISEASE

Clinical Findings

Gastroesophageal reflux (GER) is a common, almost physiologic process in infants and children.²⁹⁻³² It usually results from

Figure 115-9 Vascular impressions on trachea and esophagus on lateral view. **A.** Double aortic arch. The trachea is indented by the anterior portion of the arch and the esophagus by the posterior portion. **B.** Aberrant right or left subclavian artery. The trachea has a normal appearance. The esophagus is indented posteriorly by the anomalous vessel. **C.** Anomalous innominate artery. The trachea is flattened anteriorly by the innominate artery. The esophagus has a normal appearance. **D.** Pulmonary sling. The trachea is displaced anteriorly and the esophagus posteriorly by the left pulmonary artery, which is passing between them. E, Esophagus; S, spine; T, trachea. (Modified from Berdon WE, Baker DH: Vascular anomalies and the infant lung: Rings, slings, and other things. *Semin Roentgenol* 7:39-64, 1972.)

the failure of the lower esophageal sphincter to maintain an adequate resting pressure, but approximately 35% of children with GER may have additional disorders of esophageal motility.³⁰ GER is pathologic when it is associated with hematemesis, failure to thrive, esophageal stricture formation, apnea, and bradycardia.³¹ Additional extraesophageal or supraesophageal symptoms of GER, such as otitis media, asthma, recurrent upper respiratory tract infections, and sleep disturbances, are becoming increasingly recognized.^{29,31-34} GER is also responsible for the development of Barrett's mucosa in the esophagus.³⁵

GER can be an isolated problem, but it occurs with increased frequency in children with neuromuscular disorders; repair of tracheoesophageal fistula, diaphragmatic hernia, or gastroschisis; cystic fibrosis; and collagen-vascular diseases. Medications given to decrease bronchial spasm and to enhance aeration in children with bronchopulmonary dysplasia and asthma may reduce lower esophageal pressure, cause or worsen GER, and conversely exacerbate respiratory symptoms. Secondary GER occurs in infants and children with gastric outlet obstruction and may disappear after the obstruction is corrected. Delayed gastric emptying coexists in 50% of children with primary GER.³⁶

Although GER can be suspected on clinical grounds (i.e., infant who vomits after every feeding), some pediatricians prefer to document and quantify the reflux before beginning

Figure 115-10 Right aortic arch with aberrant left subclavian artery. **A.** Lateral view of esophagus shows pronounced posterior impression on the esophagus by the aberrant vessel (arrow). **B.** Contrast-enhanced CT shows the aberrant left subclavian artery (arrow) arising from the right aortic arch and coursing posterior to the collapsed esophagus.

Figure 115-11 Double aortic arch: MR findings. **A.** White blood, steady-state free precession image demonstrates larger right (curved arrow) and smaller left (straight arrow) aortic arches. **B.** Corresponding black blood T1-weighted image shows the double aortic arches encircling the trachea and the collapsed esophagus (arrowhead).

Figure 115-12 Pulmonary sling: MR findings. **A.** Normal anatomy. The main pulmonary artery (mpa) divides into the right (r) and left (l) pulmonary arteries. **B.** In pulmonary sling, the anomalous left pulmonary artery (l) arises from the right pulmonary artery.

therapy. Barium esophagography, the most commonly used test, is inexpensive and readily available. The greatest value of barium esophagography may be not in its ability to diagnose GER but in its ability to detect other causes of the child's symptoms and to exclude gastric or duodenal obstruction. Radionuclide scintigraphy is much less used to diagnose GER than in the past. Esophageal manometry and pH probe monitoring of the esophagus provide additional information about the frequency and duration of reflux.^{37,38} Endoscopy can document the presence and severity of GER-induced esophagitis.

Most children with isolated GER outgrow the process, but those with underlying abnormalities are less likely to do so.^{30,31,39} Symptomatic GER can be treated by thickening the infant's formula, giving smaller amounts at each meal, and positioning the infant appropriately after eating. Proton pump inhibitors and antacids are commonly given. Prokinetic agents have debatable success in treatment.³² Discontinuation of potentially provocative medications or correction of a gastric or duodenal obstruction may also eliminate GER.

Those failing to respond to medical regimens may undergo a fundoplication, which is a surgical augmentation of the lower esophageal sphincter with a gastric wrap around the lower esophagus.^{40,41} In the most common variant of the procedure, the Nissen fundoplication, the gastric fundus is wrapped 360 degrees around the esophagus; however, partial rather than complete wraps may also be performed, especially in children with poor esophageal motility.³⁹⁻⁴² Antireflux surgery produces less morbidity and is more successful in children with isolated GER than in those with a complex medical or surgical history.^{40,41} Before fundoplication is performed, it is important to exclude a lesion that interferes with gastric emptying. If one is found, the antireflux surgery may be complemented by pyloroplasty or pyloromyotomy. For certain patient populations, laparoscopic fundoplication is favored to an open procedure in many centers. The success rate of laparoscopic fundoplication is equal to that of conventional fundoplication, and benefits include shorter hospital stays, decreased need for pain medication, better cosmetic result, and earlier institution of feeding.^{39,41-43}

In some children, GER is associated with torticollis and abnormal movements of the trunk, head, and neck simulating a neurologic abnormality. This is called Sandifer's syndrome.⁴⁴ The abnormal movements cease after the GER is corrected and may be the result of the pain caused by the GER or may represent attempts to minimize reflux.

Imaging Findings

Barium Studies. To optimize detection of GER during barium esophagography, the esophagogastric junction should be challenged by an adequate amount of liquid in the stomach, and intermittent observation should be performed during several minutes. If the child refuses to drink the necessary volume of barium or has neurologic impairment of swallowing, it can be instilled into the stomach through a nasogastric tube. If the child has ingested almost as much barium as necessary then refuses to drink more, formula or juice may be given to supplement the volume. The dilution of barium does not change the ability to detect GER.

Fluoroscopy is used to define the frequency, volume, and cephalad extent of the GER (Fig. 115-13). Aspiration rarely occurs as a result of GER but may be demonstrated during the swallowing portion of esophagography. The rate at which the

Figure 115-13 Gastroesophageal reflux. A large volume of contrast material refluxes to the level of the carina. The gastroesophageal junction is patulous.

refluxed barium clears from the esophagus should be evaluated; children with rapid clearing are less likely to aspirate or to develop esophagitis.³⁰ GER-induced esophagitis is rarely seen on standard contrast studies. After the question of GER has been addressed, the stomach and duodenum should be observed to exclude delayed gastric emptying, gastric outlet obstruction, duodenal obstruction, or malrotation.

Nuclear Scintigraphy. The radionuclide scan is extremely sensitive in the diagnosis of GER. The child is given formula or juice containing technetium Tc 99m sulfur colloid (or other technetium chelate) and is continuously scanned for 60 minutes, allowing documentation of the number of reflux episodes during this prolonged time.³⁸ This is a major advantage over fluoroscopy, which must be intermittent to minimize radiation exposure to the child. The radionuclide study compares favorably with the "gold standard" of 24-hour pH probe study for gastroesophageal reflux disease and provides additional information about gastric emptying, aspiration into the lung, and abnormal esophageal contraction.^{36,38}

Ultrasound. Ultrasound can accurately demonstrate episodes of GER and correlates well with the results of barium studies and esophageal pH monitoring, but it has failed to replace other tests in the primary diagnosis of GER.⁴⁵⁻⁴⁷ The anatomy of the gastroesophageal junction is well visualized with ultrasound, which can be used in conjunction with other studies to evaluate reflux.⁴⁸ After feeding, GER is seen as retrograde passage of highly echogenic material toward the esophagus. Sonography has also been used to evaluate the length of the intra-abdominal portion of the esophagus, a factor that correlates with the likelihood of GER.⁴⁷

Figure 115-14 Barium esophagogram after fundoplication. A. The gastric wrap has produced narrowing of the distal esophagus and a mass effect on the gastric fundus (arrows). **B.** The concavity of the fundus is at the site of fundoplication.

Figure 115-15 Failed Nissen fundoplication. A. A rounded retrocardiac air collection (arrowheads) on the chest radiograph represents the herniated stomach. **B.** The abnormally located gastric fundus is filled with barium. The indentation indicates the remnants of the gastric wrap.

Postsurgical Studies. Indications for postsurgical studies include dysphagia, which may indicate that the fundoplication is too tight, and continued GER symptoms, which suggest that the gastric wrap is too loose or has become undone.⁴⁹ On radiographic examination, the intact wrap produces a mass effect at the gastroesophageal junction (Fig. 115-14). Breakdown of the wrap may be associated with paraesophageal hernia or GER (Fig. 115-15).

EOSINOPHILIC ESOPHAGITIS

Clinical Findings

During the last several decades, eosinophilic esophagitis has become increasingly recognized as a distinct form of esophagitis in children and less commonly in adults. Although this disease is manifested with symptoms that share significant overlap with those of GER, it possesses characteristic clinicopathologic features that distinguish it from GER. Clinical manifestations of eosinophilic esophagitis in children are related to esophageal dysfunction and vary by age.

Infants and toddlers often present with feeding difficulties, whereas school-aged children and adolescents are more likely to present with vomiting, pain, and dysphagia. Food impaction, which is a characteristic presentation of the disease in adults, is less commonly seen in children.⁵⁰ Eosinophilic esophagitis, which has a reported incidence in children of at least 1 in 10,000 and a high male predominance, should be suspected in children with GER symptoms who are unresponsive to conventional treatment with proton pump inhibitors.⁵¹⁻⁵³

Eosinophilic esophagitis is a chronic, immune- and antigen-mediated disease isolated to the esophagus and characterized histologically by eosinophilic inflammation.^{50,54} Endoscopy with biopsy is currently the only reliable diagnostic test for eosinophilic esophagitis, with at least 15 eosinophils per high-power field required for diagnosis.⁵⁵ In children, eosinophilic esophagitis is most often present in association with other manifestations of atopy, such as food allergy, asthma, and eczema, and is responsive to elimination of specific dietary antigens, topical steroids, or both.^{54,55}

Imaging Findings

Because the symptoms of eosinophilic esophagitis are nonspecific and often mistaken for GER, a diagnostic work-up including upper gastrointestinal examination or esophagography is frequently performed.⁵² Characteristic findings on esophagography reported in adults include long-segment, smooth mid or distal esophageal stricture and esophageal dysmotility (Fig. 115-16).^{52,53} Diffuse esophageal narrowing producing a small-caliber esophagus measuring less than 20 mm in diameter and distinctive multiple concentric indentations producing a ringed esophagus have been described in adults with eosinophilic esophagitis and can also be seen in pediatric patients.^{56,57} Schatzki rings of the distal esophagus are rare in children but, when seen, are often associated with underlying eosinophilic esophagitis.⁵⁸ Despite the plethora of radiologic abnormalities described in conjunction with eosinophilic esophagitis, the fact remains that in more than half of affected children, including those with severe symptoms and documented food impaction, the esophagram is normal, indicating that esophagography is not a reliable technique to detect this entity.⁵³

ACHALASIA

Clinical Findings

Children account for only 3% of patients with achalasia.⁵⁹ Achalasia is usually an isolated finding but may rarely be associated with syndromes. A specific association, the triple A syndrome

Figure 115-16 Eosinophilic esophagitis. Abnormally narrowed caliber of the mid and distal esophagus secondary to long-segment, smoothly marginated stricture is seen in this teenager with dysphagia. A small outpouching of contrast material (arrow) represents a localized perforation of the esophagus complicating an endoscopic biopsy.

(i.e., achalasia, alacrima, and corticotropin [ACTH] insensitivity), is also known as Allgrove's syndrome.⁶⁰

Affected children typically present with dysphagia or regurgitation of undigested food. Recurrent pneumonia may result from aspiration of esophageal contents at night by the recumbent, sleeping child. The enlarged esophagus may compress the trachea, producing airway symptoms, and weight loss or failure to thrive may develop.^{61,62}

Pneumatic dilation of the esophagus is used in some patients,⁶³ and injection of the affected esophageal segment with botulinum toxin has produced transient improvement.^{64,65} Such an injection can be repeated as necessary. In those whose achalasia is refractory to botulinum toxin injection or dilation, surgery (i.e., modified esophagomyotomy) is performed, often with laparoscopic technique.⁶⁶⁻⁶⁸ To control the frequently associated postoperative GER, fundoplication may be performed at the time of myotomy.⁶⁸

Imaging Findings

The radiologic findings of achalasia in children are similar to those of adults. Chest radiographs may show a dilated, fluid-filled esophagus that compresses or displaces the trachea, evidence of chronic aspiration, and absence of the gastric air bubble. Barium studies reveal a dilated, fluid-filled, atonic or poorly contractile esophagus that ends in a tapered, narrowed segment with beaking.

ESOPHAGEAL VARICES

Esophageal varices are rare in children, usually occurring as a consequence of extrahepatic obstruction (i.e., cavernous transformation) of the portal vein rather than parenchymal liver disease.⁶⁹ The cause of the portal venous thrombosis is unknown in most children, but there are several predisposing risk factors: dehydration, intra-abdominal infection, and umbilical venous catheterization.⁶⁹⁻⁷¹ Intrahepatic portal venous obstruction is caused by congenital or acquired diseases that produce hepatic fibrosis: biliary atresia, α_1 -antitrypsin deficiency, polycystic kidney disease, and cystic fibrosis.^{69,70}

Most commonly, the dilated venous collaterals are diagnosed at endoscopy. However, they can also be directly visualized by CT or sonography or even occasionally indirectly visualized on esophagography as tortuous, linear filling defects extending cephalad into the esophagus from the gastric fundus (Fig. 115-17).^{71,72}

FOREIGN BODY AND CAUSTIC INGESTION

Clinical Findings

Young children instinctively place objects in their mouths, and it is not surprising that most caustic and foreign body ingestions occur in children younger than 5 years. Few ingestions occur in infants younger than 6 or 7 months because infants lack the ability to place grasped objects in their mouths.

With regard to caustic ingestion, the type and location of mucosal injury depend on the pH of the ingested material.⁷³⁻⁷⁵ Caustic agents, such as lye and laundry detergents, have a high pH and cause most damage in the mouth and upper esophagus. Although most children recover without sequelae, perforation or stricture formation occurs in about 3% of patients.⁷⁴ Acids and other low-pH corrosive agents (e.g., toilet bowl cleaners) primarily injure the gastric antrum but can produce burns and

Figure 115-17 Esophageal varices. **A.** Barium esophagogram. A spot film of the esophagogastric junction demonstrates a large, linear varix. **B.** CT scan shows varices (arrows) along the posterior and medial aspects of the fluid-filled stomach.

scars in the esophagus. Contact between acid and the upper airway can produce life-threatening epiglottitis in some children. Bleaches have a neutral pH of 7 and generally cause only transient irritation of the esophagus without long-term complications. Bleach ingestion has been reported occasionally to produce deeper lesions.

In the setting of caustic ingestion, endoscopy is performed nonemergently, about 2 or 3 days after the ingestion, to assess the degree and extent of damage; this information aids in treatment and prognosis. Approximately one third of children with a history of ingestion have esophageal changes discovered by endoscopy.⁷⁵ Clinical findings (e.g., oral burns, stridor, drooling, vomiting) do not correlate with the extent of injury found endoscopically, but the number of clinical findings does correlate with the degree of mucosal damage.⁷⁶ Children with dysphagia or prolonged drooling are likely to have developed esophageal strictures or scars.

Foreign body ingestion, most commonly with coins, may be manifested with a wide range of symptoms. Children with a foreign object impacted in the esophagus may present with gastrointestinal complaints, including dysphagia, choking, and drooling. However, these children may also present with respiratory complaints, such as wheezing, respiratory distress, and cough, particularly with impaction of prolonged duration. Therefore, a high index of suspicion for esophageal foreign body should be adopted even when the ingestion is not witnessed.⁷⁷ Not infrequently, unexpected esophageal foreign bodies are discovered when a radiograph is performed for work-up of respiratory complaints. Up to 14% of children with esophageal foreign body impaction have an underlying structural abnormality, such as stricture or ring.⁷⁷ Food bolus impaction in particular has a high association with underlying esophageal disease, such as eosinophilic esophagitis.⁷⁷

Complications associated with esophageal foreign body impaction include mucosal ulceration, perforation, and fistula. These types of esophageal injury are most likely to occur when the foreign body has been present for a prolonged period exceeding 24 hours.⁷⁷ In addition, the type of foreign body may affect the likelihood of complication. Button or disc batteries, which are an increasingly common household item, are well

known to cause tissue injury when they are impacted in the esophagus. The battery can cause severe focal damage to the esophagus, sometimes within a few hours, and therefore prompt removal is imperative. Mechanisms of injury include pressure necrosis, chemical injury from fluid leaked from the battery, and low-voltage electrical injury.⁷⁸⁻⁸⁰ The 20-mm button batteries composed of lithium generate especially intense electric current that may result in particularly high rates of complications when they are ingested.⁸¹ Disc batteries smaller than 15 mm usually pass without difficulty and are less likely to cause injury.⁸⁰

Not all foreign bodies require removal. In asymptomatic children, a recently swallowed coin lodged in the esophagus below the thoracic inlet may be allowed to pass without intervention. Coin removal is necessary only when symptoms develop or serial radiographs show that the position of the coin has not changed.⁷⁶ When removal is necessary, endoscopy with rigid esophagoscopy is the preferred method.⁷⁸ Despite the need for general anesthesia, the procedure has proved to be safe and effective and can provide information about the esophagus at the site of impaction.⁸² A less frequently performed alternative is fluoroscopically guided balloon extraction, which can be a cost-effective method of foreign body removal, with reported success rates of more than 80%.^{81,83-85} When the impacted foreign body is a button battery, however, endoscopic removal is preferred because this allows determination of extent of injuries and evaluation of possible complications.⁸¹

Imaging Findings

After caustic ingestion, airway and chest radiographs should be obtained. Any swelling of the epiglottis or edema of the airway should prompt measures to ensure airway patency. Lung damage, although rare, may occur. Mediastinal air, indicating perforation of the esophagus, may not develop acutely but should be sought on early and later radiographs.

Barium studies are not useful in diagnosis or management immediately after caustic ingestion. Endoscopic evaluation of the esophagus is more precise during this period.⁷⁵ In the early recuperative period, contrast studies may show abnormalities

Figure 115-18 Lye ingestion and surgical correction. **A.** Irregularity of the distal esophagus and lack of distensibility indicate the degree of damage done by the ingestion of lye. **B.** The stricture was treated surgically by esophagectomy and colonic interposition graft. The interposed colon, coated with contrast material, is seen in the retrosternal space.

of predictive value. Retention of contrast material within the wall of the esophagus and persistent gaseous dilation of the esophagus usually signify severe injury and may precede perforation. Caustic-induced dysmotility may be associated with the appearance of transverse folds in the esophagus, and strictures can develop at these sites.^{86,87} Barium studies are of value in detecting late changes of the esophagus, such as stricture, or abnormalities in sites not visualized during endoscopy.⁸⁸ Esophagectomy with colonic interposition may be necessary to treat a long stricture or one that is resistant to dilation (Fig. 115-18).⁸⁹

Foreign bodies are easy to detect if they contain radiodense metal. Coins are the most frequently seen foreign bodies on chest radiographs.^{75,90,91} Aluminum-containing foreign bodies, especially the ring from pop-top soda cans, may be difficult to see, as are some foreign coins made from metals that are only slightly radiodense.^{92,93} Visualization of glass depends on the size of the piece ingested and on the presence of overlying structures.⁹¹ However, most swallowed foreign objects, such as food and small plastic toys, are not radiopaque and can be detected only with esophagography or endoscopy (Fig. 115-19).

Imaging work-up for suspected coin or battery ingestion should begin with anteroposterior and lateral chest radiographs for identification of type and number of the foreign body.⁷⁸ Radiographs can also aid in localization of the foreign body and of complications such as perforation. Ingested foreign bodies typically become lodged in the esophagus at several physiologic sites of narrowing, namely, the thoracic inlet, the level of the

Figure 115-19 Esophageal foreign body. Round, radiolucent filling defect in esophagus (arrow) is outlined by contrast material and represents an ingested plastic bottle cap impacted at the level of the aortic arch.

Figure 115-20 Distinguishing ingested disc battery from coin. **A.** A disc battery lodged in the distal esophagus demonstrates a distinctive appearance of two concentric densities separated by a circumferential lucent ring. **B.** In contrast, an impacted coin is homogeneous in density and lacks the characteristic features of the battery.

Figure 115-21 Esophageal perforation complicating coin ingestion. **A.** The coin is seen in the upper esophagus. The trachea is bowed anteriorly and is narrowed. **B.** After removal of the coin, the contrast study demonstrates that the coin had perforated the esophagus posteriorly and that the esophagus was pushed anteriorly by the inflammatory process surrounding the site of perforation.

aortic knob, and the gastroesophageal junction. Foreign body impaction at any other level should raise the suspicion of underlying stricture or vascular ring.

The urgency for removal of batteries from the esophagus is much higher than for coins, but coins may occasionally mimic the shape, size, and contour of round, button batteries, confounding the correct diagnosis and resulting in delayed treatment.^{78,79} Careful inspection of the radiographic features of the foreign body should be performed to discern the characteristic double density or concentric halo seen with disc batteries that distinguishes them from coins (Fig. 115-20).^{79,82}

Findings on plain radiographs of the airway or chest may be entirely normal when the esophageal foreign body is radiolucent. The mediastinum should be carefully analyzed on the lateral projection; thickening of the soft tissues between the esophagus and the trachea may be a sign of esophageal edema,

which decreases the likelihood of successful retrieval of the foreign body by catheter. Thickening or anterior bowing of the esophagus may result from mediastinitis, which develops after esophageal perforation (Fig. 115-21).

If an otherwise healthy-appearing child presents with recent onset of drooling or dysphagia, a barium study is recommended to exclude a nonopaque foreign body, a congenital lesion that has become symptomatic, or an acquired inflammatory lesion. The swallowing mechanism and common locations of physiologic narrowing should be scrutinized because these sites are where foreign bodies are most likely to lodge. After an esophageal foreign body has been removed, a contrast study may be used to exclude intrinsic esophageal disease and to detect complications, including post-traumatic esophageal diverticulum, tracheoesophageal fistula, and esophageal-aortic fistula (Fig. 115-22).^{79,94,95}

Figure 115-22 Battery-induced tracheoesophageal fistula. **A.** Lateral chest radiograph. The lodged radiopaque battery is associated with thickening of the soft tissue between the trachea and esophagus and anterior bowing of the trachea. **B.** Esophagogram. Water-soluble contrast material passes from the normal cervical esophagus into the irregular-appearing region where the battery was previously seen. The anterior collection (arrow) of contrast material indicates that perforation occurred. **C.** CT scan. After several days of antibiotics and feeding through a gastrostomy tube, the child developed a fever. A fistula (arrows) was identified between the trachea and traumatically widened esophagus.

OTHER ESOPHAGEAL INJURIES

Radiation therapy, particularly if it is combined with certain chemotherapeutic agents, can produce esophagitis, stricture, and fistula formation (Fig. 115-23).^{96,97} Motility and mucosal abnormalities are also seen acutely in children receiving chemotherapy alone. Because of immunosuppression, esophageal infections by opportunistic organisms, such as herpesvirus, *Candida albicans*, and cytomegalovirus, are common.⁹⁸ Many oral medications can produce focal esophageal injury, presumably caused by direct mucosal contact with the tablet.

Esophageal narrowing requiring dilation has been described as part of the Stevens-Johnson syndrome.⁹⁹ Esophageal involvement in epidermolysis bullosa usually takes the form of short or long, multiple or single strictures. Webs, pseudodiverticula, and overall esophageal shortening may occur in this cutaneous disorder. An increased incidence of pyloric atresia is observed among children with epidermolysis bullosa, and it appears to be localized within a genetic subgroup of those with epidermolysis bullosa.¹⁰⁰⁻¹⁰³

Figure 115-23 Radiation-associated and chemotherapy-associated esophagitis. This teenage girl received chemotherapy and radiotherapy for a lower thoracic primitive neuroectodermal tumor. The esophagogram performed because of dysphagia demonstrates a long, narrowed segment.

Diseases of the Pediatric Stomach and Duodenum

JENNIFER E. LIM-DUNHAM | RICHARD M. GORE

CHAPTER OUTLINE

Congenital Anomalies

Pyloric and Antral Atresias
Antral Mucosal Diaphragm
Microgastria
Duodenal Atresia and Stenosis
Duplication Cyst
Malrotation

Acquired Diseases

Gastric Perforation
Pyloric Stenosis
Gastric and Duodenal Hematomas
Gastric and Duodenal Foreign Bodies
Neoplasms
Peptic Ulcer Disease
Inflammatory Disorders Other Than Peptic Disease
Gastric or Duodenal Distention

Congenital Anomalies

Most anomalies that affect the stomach and duodenum are evident on plain radiographs of the abdomen. Complete atresia of the pylorus results in a single bubble of air, atresia of the duodenum is manifested as the well-known radiographic double bubble, and duplication cysts can displace or obstruct bowel. Microgastria results in absence of the normal gastric bubble and is associated with cardiovascular and splenic anomalies. When an anomaly of stomach or duodenum is encountered, careful search for other anomalies is mandatory.

PYLORIC AND ANTRAL ATRESIAS

Pyloric and antral atresias are rare anomalies in which the neonate is unable to feed without vomiting. The abdomen is gasless except for the stomach bubble. Sonograms performed on infants with pyloric atresia show neither a normal canal nor muscle of the pylorus.¹ A pyloric channel should be apparent in babies who have a complete pyloric membrane.^{2,3} The rare neonate who has pyloric stenosis has incomplete obstruction and typical features of pyloric stenosis. Differentiation between atresia and membrane usually rests with the surgeon because plain radiographs showing complete obstruction in the first day of life mandate an operation. There is an association between pyloric atresia and epidermolysis bullosa.⁴ In affected patients, minimal trauma to the skin results in blisters and erosions. Pyloric obstruction in these patients may begin in utero or develop postnatally.

ANTRAL MUCOSAL DIAPHRAGM

Complete mucosal diaphragm or web of the antrum is an uncommon anomaly that may cause vomiting or failure to thrive in infants.⁵ Older children may present because of gastric retention of a coin or other foreign body.⁶ On upper gastrointestinal studies, the thin membrane is manifested as a linear filling defect at the level of the antrum (Fig. 116-1). In symptomatic infants, the aperture of the diaphragm is often 5 mm in diameter or less, although the size of the aperture cannot be judged accurately on fluoroscopic examination.⁷ Asymptomatic, incidentally discovered webs probably do not require intervention, although some physicians advocate a more aggressive approach.^{7,8}

MICROGASTRIA

Microgastria is often associated with absence of the spleen and mesenteric abnormalities.^{9,10} An association with laryngo-tracheoesophageal clefts, tracheoesophageal fistula, and the VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb) spectrum of anomalies has been documented.^{11,12} In those patients with isolated microgastria, plain radiographs show no normal gastric air bubble and the esophagus is often dilated because it functions as an accessory stomach through reflux.¹³ The miniature stomach empties into a duodenum of normal caliber, which may be in an abnormal position (Fig. 116-2). Treatment is directed toward increasing gastric capacity by creating and attaching a jejunal pouch.¹⁴

DUODENAL ATRESIA AND STENOSIS

Clinical Findings

Atresia and stenosis are related congenital obstructive anomalies of the proximal duodenum attributable to failed canalization of the duodenum during the 8th to 10th weeks in utero. Atresia is characterized by complete luminal occlusion; stenosis is characterized by incomplete occlusion. Stenosis can take several forms, including segmental narrowing and a diaphragm or web with one or more openings partially occluding the duodenal lumen.¹⁵

Duodenal atresia has an incidence of 1 in 10,000 live births and is much more common than stenosis.¹⁶ The newborn usually has bilious vomiting because the atresia is located distal to the ampulla of Vater in 75% of patients.¹⁵ Duodenal stenosis or web, on the other hand, may not become clinically evident until later in life. The small lumen may become plugged with food only after the infant graduates from a liquid to a solid diet.¹⁷

Duodenal atresia and stenosis are associated with other anomalies, including trisomy 21, which is found in approximately one third of infants who have atresia or stenosis.¹⁵ Other

Figure 116-1 Antral web. Single-contrast view of the stomach in the prone, right anterior oblique position demonstrates a thin, linear filling defect across the barium-filled antrum (arrows). The infant presented a few hours after birth with postprandial projectile vomiting.

Figure 116-2 Microgastria. Supine, frontal view shows a miniature stomach (arrows). The moderately dilated duodenum is in the normal position. The infant had marked gastroesophageal reflux during the examination. This upper gastrointestinal series was obtained as part of an evaluation of the failure to thrive of an 8-month-old infant. The overlying catheter is a central venous line.

associations include the VACTERL spectrum of abnormalities, cardiac anomalies, and malrotation.^{16,18,19}

Annular pancreas may be found in up to 20% of patients with duodenal atresia or stenosis but is rarely the primary cause of the duodenal obstruction.¹⁵ Because the surgical approach to duodenal stenosis does not differ significantly when annular pancreas is present, an extensive preoperative evaluation is unnecessary.

Imaging Findings

Duodenal atresia and other congenital obstruction of the duodenum are reliably diagnosed with prenatal ultrasonography at or before 20 weeks of gestation.^{16,20,21} Typically, the sonogram shows a double bubble sign of fluid-filled, dilated fetal stomach and duodenum, although this observation has also been reported as a transient finding in otherwise normal fetuses (Fig. 116-3).¹⁶

After birth, the abdominal plain radiograph is usually diagnostic and shows the double bubble, with gas filling a distended stomach and proximal duodenum with no distal gas (Fig. 116-4). The radiograph may be nondiagnostic if the stomach and duodenum are decompressed by vomiting or a nasogastric tube. If plain radiographs are not diagnostic, air or barium can be injected through the nasogastric tube. In incomplete duodenal obstructions, a double bubble is accompanied by gas in distal bowel.^{16,22} An important condition that may mimic duodenal atresia or stenosis on plain radiographs is malrotation with midgut volvulus.

Infants with clinical and plain radiographic evidence of complete or partial high-grade duodenal stenosis will rarely require additional imaging with contrast upper gastrointestinal examination because surgical intervention is required to relieve the obstruction. Surgery can be delayed if necessary for duodenal atresia or stenosis but not for malrotation and midgut volvulus. If a delay in surgery is contemplated, upper gastrointestinal

Figure 116-3 Duodenal atresia prenatal ultrasound. Abnormally dilated and fluid-filled stomach (arrowhead) and duodenal bulb (arrow) suggest duodenal atresia in this fetal ultrasound obtained at 29 weeks of gestation.

Figure 116-4 Duodenal atresia. **A.** Abdominal radiograph of a newborn infant shows the classic double bubble with dilated, air-filled stomach and duodenum. **B.** Upper gastrointestinal examination shows the duodenum dilated out of proportion to the stomach, a characteristic appearance for duodenal atresia, and complete obstruction of passage of contrast material beyond the level of the atretic segment (arrow).

examination or ultrasound should be performed to confirm absence of malrotation.²²

Complete obstruction of the duodenum with failure of contrast material to pass beyond the atretic segment and duodenal bulb dilation out of proportion to the stomach are typical findings on upper gastrointestinal examination in atresia. In duodenal stenosis, narrowing of the second portion of the duodenum is seen, but the corkscrew appearance of the duodenum and displacement of the duodenojejunal junction (DJJ) seen in malrotation and volvulus are absent.²² Duodenal diaphragm or web, which may also be called intraluminal diverticulum, appears as a fine linear filling defect within the barium-filled duodenum (Fig. 116-5).²³ In older children, the diaphragm that has been stretched for years may take on the appearance of a windsock on both barium and ultrasonographic studies.²⁴

DUPLICATION CYST

Clinical Findings

Duplication cysts are rare in the stomach and duodenum.²⁵⁻²⁷ Duplications that arise from the gastroesophageal junction may contain respiratory and enteric tissue, and they probably represent a bronchopulmonary foregut malformation.^{25,28} If a cystic mass is discovered at the gastroesophageal junction, chest radiographs should be scrutinized for a mediastinal or pulmonary component to the cyst. Duplication cysts of the distal stomach and duodenum may be enteric or neurenteric in origin.²⁶ In early intrauterine life, a neurenteric canal connects ectoderm to endoderm and passes through dorsal neural folds. Persistence of this or an accessory canal (i.e., split notochord syndrome) gives rise to a series of anomalies, including diastematomyelia, hemivertebrae, and enteric cysts.²⁹ Most gastric and duodenal cysts are considered the result of abnormal canalization of the intestinal tract.³⁰ Duplication cysts are often diagnosed prenatally.^{31,32}

The common features of gastric or duodenal duplication cysts include obstruction, palpable upper abdominal mass, gastrointestinal bleeding, and respiratory distress. Most duplication cysts are diagnosed during the first year of life.^{32,33-35}

Figure 116-5 Duodenal diaphragm or web. The partially obstructing duodenal web is seen as a thin linear filling defect in the second portion of the duodenum (arrow).

Imaging Findings

Gastric duplication cysts can be evaluated by upper gastrointestinal examination, ultrasonography, or both (Fig. 116-6). At fluoroscopy, a “beak” results when contrast material in the gastrointestinal tract lumen surrounds the proximal portion of an obstructive duplication cyst.^{36,37} On ultrasound, enteric duplication cysts can usually be recognized by a characteristic pattern of echoes in the bowel wall, which mirrors that seen in the native bowel. This pattern has been termed the gut signature and consists of an inner hyperechoic ring representing mucosa

Figure 116-6 Gastric duplication cyst. **A.** Upper gastrointestinal examination in this 7-week-old infant with persistent vomiting shows extrinsic compression and mass effect on the gastric antrum and severe luminal narrowing of the proximal duodenum (arrow) with nearly complete obstruction. **B.** Corresponding sonogram confirms that the mass effect is caused by a large, bilobed cyst containing low-level internal echoes. The cyst wall exhibits the characteristic alternating hypoechoic and hyperechoic layers of bowel wall.

and submucosa and an outer hypoechoic ring representing muscularis propria.^{33,34,38}

MALROTATION

Clinical Findings

The developing gastrointestinal tract normally has two zones, the duodenojejunal and the cecocolic, that seem to be able to pull adjacent bowel along with them. Before the 8th week of intrauterine life, the duodenojejunal segment returns to the peritoneal cavity from the omphalus, having coursed counterclockwise to the left of the midline, under the superior mesenteric artery (SMA). Later, after the 10th week of life, the cecocolic segment undergoes a counterclockwise rotation toward the right lower quadrant.³⁹⁻⁴¹ Intestinal malrotation refers to improper completion of the normal rotational process, resulting in formation of abnormal mesenteric attachments (i.e., Ladd's bands) and shortening of the mesenteric base. Arrest of rotation may occur at any phase of development or involve only a part of the midgut, resulting in a wide spectrum of rotational anomalies ranging from nonrotation (in which the small bowel lies to the right of the mesenteric vessels and the colon to the left) to minor degrees of cecal elevation.⁴¹⁻⁴³

Particular attention should be paid to two critical anatomic landmarks in malrotation. First is the ligament of Treitz, which is a suspensory ligament of connective tissue and smooth muscle that runs from the root of the SMA to the junction of the fourth portion of the duodenum with the jejunum.^{41,44} Its presence is inferred on an upper gastrointestinal examination by normal position of the duodenal-jejunal junction (DJJ) in relation to the stomach, proximal duodenum, and spine. The DJJ and ligament of Treitz are located in the left upper quadrant of the abdomen in normal individuals but are displaced medially and inferiorly in those with malrotation.⁴⁵ Second is the third and fourth portions of the duodenum, which are fixed in the retroperitoneum under the SMA in normal individuals but freely movable in the peritoneal cavity in those with malrotation.⁴⁶

It is not the malrotation that causes symptoms but rather complications arising from the malrotated, abnormally

positioned intestine. The most grave is a midgut volvulus that results from twisting of the mesentery around the abnormally narrowed and shortened vascular pedicle. Volvulus may be fixed or intermittent and is a life-threatening emergency because of potential for bowel ischemia and necrosis.⁴⁷ Obstruction may also result from Ladd's bands across the duodenum. Affected individuals are usually symptomatic in the first year of life, but malrotation can be manifested at any age.⁴⁵ Bilious emesis is the classic symptom, and a high index of suspicion for malrotation and volvulus should be maintained for those infants presenting in this manner.^{43,45} On occasion, a child may tolerate obstruction from intermittent volvulus and come to medical attention because of episodic pain or symptoms of malabsorption.^{48,49} Chronic, intermittent volvulus is a cause of secondary lymphangiectasia and chylous ascites.

Urgent surgical treatment of malrotation is indicated to avoid the potentially catastrophic complications of bowel necrosis associated with volvulus. The definitive treatment is Ladd's procedure, in which the midgut volvulus is untwisted, Ladd's bands are divided, cecum is mobilized, appendix is removed, and mesentery is widened, with placement of small bowel in the right hemiabdomen and colon in the left hemiabdomen.⁵⁰

Imaging Findings

Plain radiographs of patients with malrotation or volvulus show a variety of appearances ranging from paucity of distal bowel gas to unusual position of the air-filled stomach or intestinal loops, gaseous dilation of the stomach or duodenal bulb due to obstruction, and grossly distended air-filled loops with mural thickening if there is a closed-loop distal bowel obstruction and ischemia from volvulus. Most often, however, the findings on plain radiography are normal.^{44,45}

There is considerable debate in the literature concerning the best diagnostic approach to document position of bowel and presence of obstruction in suspected midgut volvulus.⁵¹⁻⁵⁴ The methods described in the following paragraphs are not foolproof, and ultimately, because the stakes of missing a malrotation are so high, in inconclusive cases, the radiologist should

not hesitate to repeat a study or to use a different, complementary modality to reach the correct diagnosis.^{44,45,55}

A carefully controlled upper gastrointestinal series, with delivery of barium or water-soluble contrast material orally or through a nasogastric tube placed in the stomach or, better yet, in the proximal duodenum, is generally considered the “gold standard.”^{45,55} The critical anatomy to document is the DJJ in a well-positioned straight frontal view of the first passage of contrast material through the duodenum.^{55,56} The DJJ, and by inference the ligament of Treitz, is considered normal when it is at or above the level of the superior end plate of the L2 vertebral body or the duodenal bulb and to the left of the left pedicle of this vertebral body.^{41,57} On lateral views, the second and third portions of the duodenum are posterior because they are retroperitoneal.^{45,55,56}

Displacement of the DJJ inferiorly or medially on the anteroposterior view and anteriorly on the lateral view is a sign of malrotation (Fig. 116-7). Ladd’s bands typically cause a complete or partial obstruction of the duodenum; midgut volvulus causes a corkscrew, Z, or ribbon-like appearance of the duodenum and jejunum, sometimes with proximal dilation and partial obstruction of the duodenum (Fig. 116-8).^{39,40,41,54}

On occasion, normal anatomic variations of the duodenum may be difficult to distinguish from genuine malrotation, or the DJJ may not be visualized because of technical factors. Normal variations that may mimic malrotation include inferior displacement of the DJJ by dilated stomach or bowel in infants with gastric overdistention or distal bowel obstruction; mobility of the DJJ in children younger than 4 years; and redundancy of

Figure 116-7 Malrotation. Upper gastrointestinal examination shows abnormally positioned duodenojejunal junction (arrow) to the right of the left pedicle and below the level of the L2 vertebral body superior end plate.

Figure 116-8 Malrotation with midgut volvulus.

A. Abdominal radiograph of a 3-week-old boy who presented with bilious vomiting, lethargy, and bloody stools shows abnormal dilation of the duodenum (arrows) and multiple dilated loops of small bowel with thickened walls. **B.** Duodenal obstruction with beaking of the barium is caused by the twisted bowel. **C.** Radiograph taken a few minutes later shows the typical corkscrew appearance of the duodenum and proximal jejunum associated with malrotation and midgut volvulus.

the second portion of the duodenum, also known as mobile duodenum or water-trap duodenum.^{48,57-60} In cases in which the position of the DJJ is equivocal, the position of the cecum can be evaluated by either following the contrast material into the colon or performing a contrast enema.^{44,59} However, the cecum, although usually located in the right lower quadrant, may have a wide range of normal in infants and may be in a normal position even with malrotation.^{39,40,44} Of children with surgically proved malrotation, only 87% had an abnormally positioned cecum compared with 97% with an abnormally positioned DJJ.⁴⁵

Several sonographic features of malrotation have been described. Inversion of locations of the SMA and superior mesenteric vein (SMV) is one finding that has been described in malrotation. The SMV usually lies to the right of the SMA on a transverse image at the level of the junction with the portal vein. If the SMV is to left of the SMA, the diagnosis of malrotation should be entertained. However, this is an inconstant finding, with sensitivity of 67% to 100% and specificity of 75% to 83%, and normal relationships are present in malrotation and inverted relationships are present without malrotation.^{44,45,56} The whirlpool sign, indicating a midgut volvulus, can be seen on ultrasound when the bowel, SMV, and SMA are twisted and wrapped around the vascular mesentery (Fig. 116-9). Finally, sonographic demonstration of the third portion of the duodenum in a retroperitoneal position between the SMA and the aorta is a reliable but not infallible sign of normal intestinal rotation.^{43,46,56} Likewise, absence of a retroperitoneal duodenum is a strong indicator of malrotation.⁴⁶

After Ladd's procedure for malrotation and volvulus, upper gastrointestinal examination shows the expected postoperative appearance of persistently displaced DJJ, small bowel in the right hemiabdomen, and colon in the left hemiabdomen (Fig. 116-10).⁵⁰ Other possible complications include adhesions and small bowel obstruction, reported in up to 24% of patients, and recurrent volvulus, reported in up to 7% of patients.⁵⁰

Acquired Diseases

GASTRIC PERFORATION

The incidence of acute spontaneous gastric perforation in neonates is declining.^{61,62} Predisposing factors include acute distention of the stomach, ischemic necrosis associated with perinatal asphyxia, and distal obstruction such as annular pancreas or

Figure 116-9 Malrotation with midgut volvulus. Transverse color Doppler sonogram of an epigastric mass shows the whirlpool sign consisting of the SMA (arrow) and SMV (arrowhead) twisted and draped clockwise around the mesentery, indicating midgut volvulus.

Figure 116-10 Ladd's procedure for malrotation. **A.** Small bowel examination shows the expected postoperative appearance after Ladd's procedure with jejunum and ileum located in the right upper quadrant. **B.** The entire colon, including the rectosigmoid (arrow) and the cecum (arrowhead), is located in the left hemiabdomen.

duodenal stenosis.⁶¹⁻⁶⁵ Plain radiographs show pneumoperitoneum and absence of a gastric air-fluid level on upright views.⁶⁶ Neonatal duodenal perforation is rare.⁶⁷

Gastric perforation in older children occurs in the following clinical settings: perforated peptic ulcer, dermatomyositis (although duodenal perforation is more common), migration of tubes and catheters through the gastric wall, and prior ingestion of caustic substances.⁶⁸⁻⁷² Complications of the Nissen and other funduplications include gastric bloat and gastric rupture or infarction when patients also have distal small bowel obstruction.⁷³⁻⁷⁵ Blunt trauma to the upper abdomen, when the stomach is distended, occasionally results in gastric rupture.

PYLORIC STENOSIS

Clinical Findings

Hypertrophic pyloric stenosis, which occurs in approximately 3 of 1000 infants, is one of the most common indications for surgery in infants. This disorder with familial predisposition is of unknown etiology but probably results from a complex interaction of genetic and environmental factors.^{76,77} Males, especially first-born males, are affected more frequently.^{78,79}

Classically, pyloric stenosis is manifested in a previously healthy infant between the age of 2 and 12 weeks with repeated nonbilious emesis that is sometimes forceful or projectile. The gradual onset of the symptoms may be mistaken for new or worsening gastroesophageal reflux. Presentation outside of this age range or emesis that is bilious should prompt evaluation for alternative diagnoses, such as malrotation. Pyloromyotomy, which can be performed nonemergently, is the treatment of choice for pyloric stenosis.⁷⁶ Because of better cosmetic result, shorter hospital stays, and lower wound infection rates, laparoscopic surgery is increasingly favored over an open procedure.^{76,78}

Imaging Findings

Ultrasonography is the established imaging examination for the diagnosis of pyloric stenosis and has been found to be highly sensitive and specific.⁷⁶⁻⁷⁸ In contemporary medical practice, the reliance on imaging has progressed to the point that ultrasound is now considered an intrinsic part of evaluation for pyloric stenosis, whereas the classically described palpable "olive" is found on physical examination with decreasing frequency.^{76,80,81} Features easily depicted by sonography include a thickened, hypoechoic pyloric muscle (doughnut or cervix sign) and a double layer of redundant echogenic mucosa (sonographic double-track sign) (Fig. 116-11).^{77,82-84} A muscle thickness of more than 3.0 to 3.5 mm measured in the long axis of the pylorus is a reliable indicator of pyloric stenosis, regardless of the patient's age or weight.^{52,76,79,85-87} A pyloric channel length of more than 15 to 18 mm is also considered abnormal.⁸² As important as the quantitative measurements in diagnosis of pyloric stenosis is the morphologic appearance of the pylorus and the real-time observation of little or no passage of gastric contents through the pylorus.

In pyloric stenosis, the thickened muscle is a fixed abnormality that does not change with time. Pylorospasm, which is a condition in which the muscle enlargement is transient rather than fixed and which is treated nonoperatively, may mimic pyloric stenosis on sonography. The muscle may be thickened, but the degree of thickening is often less pronounced than in pyloric stenosis, usually less than 3.0 mm. In addition, whereas

Figure 116-11 Pyloric stenosis: ultrasonography. In this image obtained along the long axis of the pylorus, the hypoechoic pyloric muscle (between calipers) is abnormally hypertrophied and thickened, measuring more than 3.5 mm, and can be seen on either side of the parallel, linear echoes (arrow) that represent the redundant mucosa of the narrowed pyloric channel. The gallbladder (GB) is a useful anatomic landmark for locating the pylorus.

muscle thickening is persistent in pyloric stenosis, it is intermittent in pylorospasm, with occasional relaxation of the pyloric muscle allowing passage of gastric contents. Thus, extending the length of time of observation of the pylorus to at least 5 to 10 minutes is an essential part of the sonographic study that can prevent false-positive diagnosis of pyloric stenosis.⁸⁴ In equivocal cases, repeated sonography in 1 to 3 days can be performed to detect early or evolving pyloric stenosis.⁷⁶⁻⁷⁸

Sonography should be performed with a high-frequency linear array transducer placed with the liver as an acoustic window.⁷⁷ To allow adequate filling of the antrum with fluid and assessment of patency of the pyloric channel, the infant can be turned to the right posterior oblique position and fluid can be given orally (Fig. 116-12). These maneuvers can help demarcate the landmarks denoting the beginning and end of the pyloric channel, namely, the prepyloric antrum and the duodenal bulb.⁷⁷ Fluid should not be given if the stomach is already distended as an overdistended stomach displaces the pylorus behind the stomach, making visualization difficult and possibly leading to false-negative results.⁷⁷

Contrast upper gastrointestinal examination is rarely performed if pyloric stenosis is the primary diagnostic consideration, but radiologists should still recognize findings because unexpected pyloric stenosis is occasionally found in infants undergoing upper gastrointestinal examination for suspected reflux. Upper gastrointestinal examination is also an alternative examination in the event that sonographic expertise is not available.⁷⁶ The classic features of pyloric stenosis on barium radiography include partial or complete gastric outlet obstruction, hyperperistalsis of the stomach, elongation of the pyloric channel, single (i.e., string sign) or double (i.e., train track sign) streaks of barium within the compressed lumen of the

Figure 116-12 Pyloric stenosis: ultrasonography. Gastric outlet obstruction secondary to hypertrophied pyloric muscle. The stomach is distended with fluid given orally. The pyloric channel (between calipers) is abnormally elongated to more than 17 mm and does not open to allow passage of fluid. Reliable sonographic landmarks demarcating the beginning and end of the pylorus are the fluid-filled gastric antrum (arrow) and the echogenic, triangular duodenal bulb (arrowhead), respectively.

channel, and the shoulder sign of a pyloric mass indenting the barium-filled stomach and the base of the duodenal bulb (Fig. 116-13).^{76,82}

The radiographic appearance in the immediate postoperative period after pyloromyotomy is difficult to interpret because it is similar to that of preoperative studies, with a string sign and antropylorospasm (Fig. 116-14).⁷⁶ By 6 weeks, however, the sonographic and radiographic appearance should be normal for most patients. Until then, there is often asymmetry of the channel as the mucosa eventrates through the defect of the “cracked” muscle. Incomplete pyloromyotomy results in persistence of an elongated, narrowed channel with poor gastric emptying.⁸⁸ Patients who have had a past history of successful pyloromyotomy may be left with some antropyloric dysfunction, which has led to retention of foreign bodies (e.g., coins) in some patients.^{76,89}

GASTRIC AND DUODENAL HEMATOMAS

Clinical Findings

Gastric hematoma from blunt abdominal trauma is unusual. Duodenal hematoma is more common because the duodenum is sandwiched between the spine and the anterior abdominal wall of the epigastrium. A typical history in such cases is a child falling onto the handlebars of a bicycle or being struck in the abdomen during play or an athletic event.^{90,91} Duodenal hematomas are associated with pancreatic injury because the pancreas is also located in the retroperitoneum in a position vulnerable to blunt epigastric trauma.⁹²

Child abuse should be considered when any child has a suspicious history.^{93,94} Other risk factors for duodenal hematoma

include Henoch-Schönlein purpura, bleeding associated with leukemia, coagulopathies, idiopathic thrombocytopenia purpura, endoscopic biopsy, and anticoagulant therapy.⁹⁵ Surgery is mandatory when perforation is present, but otherwise most uncomplicated duodenal hematomas are managed conservatively.^{90,94,96}

Imaging Findings

The diagnosis of duodenal hematoma can be suggested by plain radiographs that demonstrate gastric distention, soft tissue mass in the right hemiabdomen, and sparse distal gas. Retroperitoneal air can be seen on the plain radiograph or computed tomography (CT) scan as a sign of transmural leakage.⁹⁶⁻⁹⁸ Upper gastrointestinal study with contrast material shows the intramural mass effect of the hematoma but may not demonstrate the perforation if the hematoma is plugging the mural rent (Fig. 116-15A).

Ultrasonography can demonstrate and monitor the hematoma and adjacent pancreatic injury that is commonly present, but it cannot reliably demonstrate perforation (Fig. 116-15B).^{92,99} CT is the preferred method of imaging if there has been severe upper abdominal trauma, especially crush injury, because it can image all organs well (Fig. 116-16).⁹⁶ However, CT can miss subtle cases of duodenal rupture.¹⁰⁰ As the hematoma resolves, perforation and duodenal diastasis may become apparent, and every child with a duodenal hematoma must be carefully watched during the first 7 to 10 days after trauma.⁹⁹

GASTRIC AND DUODENAL FOREIGN BODIES

Clinical Findings

A gastric mass in a child can be an ingested foreign body or a bezoar. The most common bezoar in childhood is a trichobezoar, or hairball, but other indigestible materials, such as vegetable or fruit (phytobezoar), may also form a mass that may cause obstruction.¹⁰¹ Trichobezoar in adolescence is usually associated with psychiatric problems and pica, which is ingestion of non-nutritive substances. The trichobezoar is usually confined to the stomach, but a tail may extend into the duodenum and, rarely, throughout the small bowel.¹⁰² Lactobezoars have been described in premature infants, and they probably form as a result of immature mechanisms of gastric emptying.¹⁰³ The symptoms of bezoars are usually those of insidious obstruction, such as nausea, vomiting, abdominal pain, early satiety, and decreased appetite.^{101,102}

Ingestion of foreign bodies is extremely common in young children, particularly in those between the ages of 6 months and 3 years. Because most objects pass without complication, even in small children, a conservative approach is taken by surgeons and pediatricians. Of foreign bodies that reach the stomach, 90% to 95% pass spontaneously in the absence of underlying stomach and duodenum structural abnormality.¹⁰⁴⁻¹⁰⁶

Because of unfavorable size, shape, or composition, several types of ingested foreign bodies are more likely to cause complications and should be approached with more caution than for other types of foreign bodies. These include sharp pointed objects, objects longer than 6 cm, disc batteries, and magnets.¹⁰⁶

Ingested disc or button batteries can potentially cause injury because prolonged contact of the battery with tissue is known to cause focal injury and possible perforation due to pressure necrosis or low-voltage electrical injury.¹⁰⁶ Although batteries

Figure 116-13 Pyloric stenosis: upper gastrointestinal series. **A.** Abdominal radiograph in a 5-week-old boy with a 1-week history of postprandial, nonbilious vomiting shows gastric distention with relative paucity of gas distally. **B.** A single streak of barium (the string sign, arrow) within the narrowed, elongated pyloric channel is seen. Anatomic landmarks confirming that this is pylorus are the gastric antrum proximally (An) and the duodenal bulb distally (arrowhead). **C.** Parallel double streaks of barium (i.e., train track sign) within the abnormal pyloric channel and indentation on the barium-filled stomach and duodenal bulb are from the thickened pyloric muscle.

are more likely to lodge in the esophagus than in the stomach, if a battery fails to pass beyond the stomach after several days, removal is recommended.¹⁰⁶ Management of disc batteries impacted in the esophagus is discussed in Chapter 115.

Ingested rare earth magnets that are small but powerful have become increasingly recognized as a potential cause of gastrointestinal injury that requires active management. Two or more magnets or a magnet coupled with a metallic foreign body may lodge in two adjacent but separate segments of the gastrointestinal tract and adhere to each other because of magnetic attraction, resulting in entrapment, necrosis, and perforation of the interposed bowel wall.¹⁰⁶⁻¹⁰⁸ Although most commonly this occurs in the small bowel, any segment of intestinal tract from esophagus to colon can be affected. In the setting of abdominal pain or other clinical signs of obstruction or perforation, the threshold is low for endoscopic removal of the magnets within endoscopic reach and possible surgical removal for those beyond endoscopic reach.¹⁰⁶

Imaging Findings

Large trichobezoars in the stomach can often be visualized on plain radiographs and confirmed with barium upper gastroin-

testinal examination (Fig. 116-17). They may also be incidentally discovered on cross-sectional imaging.

In cases of suspected foreign body ingestion, witnessed ingestion and reliable history are often absent, making plain radiographs an important part of management. Anteroposterior and lateral radiographs of the chest and abdomen are recommended to confirm the presence, type, and location of the foreign body and evidence of perforation, such as free intraperitoneal air. Care should be taken not to mistake a round disc battery, which has a characteristic beveled, double density rim or edge on plain radiographs, with a coin. Sequential radiographs should be obtained several hours apart to document movement of the foreign body through the gastrointestinal tract. In the case of multiple magnets or a combination of magnet and metallic foreign body, failure of movement of the foreign body or presence of a gap between two magnets should raise suspicion of bowel wall entrapment between the objects and need for intervention (Fig. 116-18). Pitfalls in plain film interpretation include stacked magnets simulating a single object and assuming that adhered magnets are located in a single segment of bowel without intervening bowel wall.¹⁰⁶

NEOPLASMS

Gastric and duodenal neoplasms are rare in children. There are a wide variety of masses arising from the stomach that overlap significantly in imaging characteristics and are difficult to distinguish from each other radiographically.¹⁰⁹ Masses arising external to the stomach, such as large pancreatic pseudocysts or hepatic masses, can also indent the stomach, causing mass effect, and mimic a gastric mass.

Gastric teratomas occur in infancy, most commonly in boys.¹¹⁰ Virtually all of these patients present with upper abdominal masses during the first year of life.¹¹¹⁻¹¹⁴

Figure 116-14 Postoperative pyloromyotomy. There is residual deformity of the pylorus but normal gastric emptying after surgery for pyloric stenosis. The follow-up examination was performed for persistent "spitting" postoperatively. The patient responded to conservative medical therapy.

Plain radiographs typically show calcification within a mass that displaces the gastric air bubble.¹¹³ Without cross-sectional imaging, differentiation from retroperitoneal neuroblastoma may be difficult in some patients. Leiomyomas and leiomyosarcomas are lobulated or polypoid masses arising from the gastric wall that can be differentiated only by histologic examination.^{115,116} Leiomyoblastoma is an uncommon tumor of the gastric wall that tends to grow in an intraluminal fashion, causing ulceration of the overlying mucosa. Its biologic behavior is generally benign, but metastases have been reported, with the liver being the most frequent site.¹¹⁷

Other rare tumors of the stomach include lymphoma, which may be a primary lesion or, rarely, part of generalized involvement with Burkitt's lymphoma.^{118,119} In either case, the appearance is similar: diffuse infiltration of the gastric wall, mucosal thickening, ulcerations, and a discrete gastric mass. Gastric adenocarcinomas, which appear similar to lymphoma and leiomyosarcoma on barium studies, are unusual in children and are associated with ataxia-telangiectasia and

Figure 116-16 Duodenal hematoma. CT scan shows the duodenal hematoma (arrow) in the wall of the second portion of the duodenum, which causes eccentric compression of the contrast-filled lumen.

Figure 116-15 Duodenal hematoma. A. Prone, oblique view from an upper gastrointestinal series shows duodenal obstruction with barium (arrows) outlining a duodenal mass. **B.** Transverse sonogram of the upper abdomen demonstrates the mass to be a duodenal hematoma (arrows) in this 10-year-old child who sustained a bicycle handlebar injury to the upper abdomen. The complete sonographic study also demonstrated pancreatic swelling and peripancreatic fluid from the injury (not shown).

immunodeficiency.^{120,121} Gastrointestinal stromal tumor, a mesenchymal malignant tumor of the gastrointestinal tract, involves the stomach in more than 50% of cases (Fig. 116-19).^{109,122}

Gastric inflammatory pseudotumor can simulate a malignant tumor on radiographic studies and should be considered when a gastric mass contains an ulcer or confined perforation; if the child has another unusual associated problem, such as retroperitoneal fibrosis or sclerosing cholangitis; or if the child has Castleman's syndrome.¹²³

Polyps of the stomach and duodenum are most commonly hamartomatous and part of the Peutz-Jeghers syndrome (Fig. 116-20). Fundic gland polyposis has been described in children

and adults who have familial adenomatosis coli and Gardner's syndrome.¹²⁴ Other gastric polyps in children include inflammatory fibroid polyp, solitary hyperplastic polyp, and polypoid focal foveolar hyperplasia.¹²⁵⁻¹²⁸

Neurofibromas can develop in the gastric or duodenal wall. Although these lesions usually are benign, they can cause vomiting, jaundice, and hematemesis.¹²⁹ Neurofibromas usually occur with other stigmata of von Recklinghausen's

Figure 116-17 Trichobezoar. There is a large filling defect within the barium-filled stomach of this 12-year-old girl with a 2-year history of trichophagia, which left bald patches on her head. At surgery, a 500-g mass of matted, brunette hair was removed from the stomach.

Figure 116-18 Ingested magnets in the stomach. Ten magnetic balls arranged in a linear mass in the expected region of the gastroesophageal junction and proximal stomach are seen in this patient with several days of acute abdominal pain. At endoscopy, the separate magnets had adhered together, with the most proximal magnet in the distal esophagus and the others in the gastric cardia, entrapping esophageal and stomach wall between them. There was no bowel wall erosion or perforation.

Figure 116-19 Gastrointestinal stromal tumor of stomach. **A.** The upper gastrointestinal series demonstrates a large filling defect (arrow) in the gastric fundus. **B.** CT scan shows the fundal, intraluminal soft tissue mass (arrow represents the tumor outlined by contrast material in the stomach).

Figure 116-20 Peutz-Jeghers syndrome. Barium and air administered through a gastrostomy tube in this patient with known Peutz-Jeghers syndrome outline multiple filling defects representing hamartomatous polyps.

disease. Pancreatic rests, manifested as masses along the greater curvature of the stomach or inner margin of the duodenum, are congenital abnormalities that are rarely diagnosed in infancy.¹³⁰ Choledochoceles may be manifested as a smooth, well-defined mass at the ampulla of Vater. Intussusception of the duodenum or stomach can occur when a large hamartomatous polyp, gastrostomy tube, or Foley catheter acts as a lead point.¹³¹

PEPTIC ULCER DISEASE

Helicobacter pylori, a gram-negative, motile bacterium, is a common human pathogen associated with peptic ulcer disease and gastritis, with reported incidence of up to 50% in lower socioeconomic classes in the United States.¹³²⁻¹³⁶ Whereas most infections are acquired during childhood, symptoms typically are not manifested for decades, and consequently peptic ulcer disease in children is remarkably uncommon.¹³⁶⁻¹³⁸ Perforated peptic ulcer disease is even more uncommon, with one series spanning 20 years reporting only 52 cases and describing characteristic acute rather than chronic presentation and association with an older, adolescent-age group and male gender.¹³⁹

Peptic ulcer disease may also occur secondary to stress in infancy and early childhood. Shock, respiratory failure, sepsis, hypoglycemia, severe burns (i.e., Curling's ulcer), intracranial lesions (i.e., Cushing's ulcer), and chronic systemic disease have been implicated in addition to aspirin, other nonsteroidal anti-inflammatory drugs, corticosteroids, and tolazoline.^{68,138}

Zollinger-Ellison syndrome, which is due to excessive gastrin production by gastrinoma and resultant gastric acid hypersecretion, is a rare cause of peptic ulcer disease in children; the registry tabulating this disease recorded only 28 children in 21

years.^{68,136} Peptic ulceration, gastric acid hypersecretion, and hypergastrinemia have occasionally occurred in children with antral G-cell hyperplasia.⁶⁸

INFLAMMATORY DISORDERS OTHER THAN PEPTIC DISEASE

Ménétrier's disease is a rare inflammatory disorder characterized by enlarged gastric folds, predominantly in the body and fundus, and proliferation of gastric glands.¹⁴⁰⁻¹⁴² This disease has a bimodal distribution, occurring in children younger than 10 years and also in adulthood. In contrast to the progressive clinical course of the disease in adults, the childhood form of the disease is linked to cytomegalovirus infection and has an acute onset with spontaneous resolution in weeks or months.¹⁴¹ Affected children present with upper abdominal pain, nausea, and vomiting that is occasionally complicated by hematemesis, anemia, and marked hypoproteinemia. Abnormally thickened gastric folds and gastric wall thickening can be seen with barium studies, CT, or sonography.¹⁴⁰⁻¹⁴⁴

Eosinophilic gastritis and eosinophilic gastroenteritis are classified within the larger group of primary eosinophilic gastrointestinal disorders in children characterized by eosinophil-rich inflammation of the gastrointestinal tract without known cause.^{145,146} Eosinophilic esophagitis, which is also subsumed in this classification, is discussed in more detail in Chapter 115. An allergic mechanism, including generalized atopy and food allergy, is proposed in at least a large subset of children with eosinophilic gastritis and eosinophilic gastroenteritis who may have a history of asthma, eczema, or allergic rhinitis in addition to exhibiting a variety of nonspecific symptoms including abdominal pain, vomiting, failure to thrive, anemia, and protein-losing enteropathy.^{145,146} Imaging has low sensitivity and specificity, but findings in the stomach include mucosal irregularity and lacy pattern, gastric fold and wall thickening, and luminal narrowing, usually confined to the gastric antrum.^{145,147,148}

Chronic granulomatous disease is a hematologic disorder, usually occurring in boys, in which there is a defect in the mechanism for producing superoxide. This results in ineffective lysis of certain bacteria by polymorphonuclear leukocytes and mobilization of macrophages and other granulomatous responses. In addition to the well-known infectious complications of the disease, involvement of any portion of the gastrointestinal tract has been reported in a large number of patients.^{149,150} The most characteristic gastrointestinal tract finding, fold and wall thickening of the gastric antrum that may lead to luminal narrowing and gastric outlet obstruction, is found in only 16% of cases (Fig. 116-21).¹⁵⁰⁻¹⁵²

Crohn's disease affecting the stomach and duodenum is unusual in children and, if present, usually is found in patients with well-established small bowel and colonic disease.¹⁵³⁻¹⁵⁵ Mucosal nodularity and ulceration, fistula and sinus tracks, and irregular narrowing and pseudodiverticula formation are the major radiographic findings in gastroduodenal Crohn's disease (Fig. 116-22).¹⁵⁵

The most common sites of gastrointestinal involvement of Henoch-Schönlein purpura are the duodenum and small bowel, which is discussed further in Chapter 117. Thickening of the wall of the duodenum, usually the second portion of the duodenum, is seen and may rarely be accompanied by ulceration.¹⁵⁶⁻¹⁵⁸ The characteristic rash may appear after abdominal symptoms of pain and vomiting.

Figure 116-21 Chronic granulomatous disease. Thickened gastric folds with marked antral narrowing are seen in this patient with a long-standing history of chronic granulomatous disease. This study was prompted by symptoms of epigastric discomfort and vomiting.

Figure 116-22 Gastritis in Crohn's disease. A 12-year-old boy presented with upper abdominal pain and weight loss. Mucosal nodularity is apparent on this radiograph from an upper gastrointestinal series.

Twenty-five percent of the world's population harbor *Ascaris lumbricoides*, and most infected people are children.¹⁵⁹ This is the only parasite that ingests barium.¹⁵⁹ When the worm burden is sufficiently large, obstruction can result, and radiologists working in endemic areas become skilled at differentiating clumps of intraluminal worms from stool and other masses (Fig. 116-23). Gastric mucosal penetration by the larvae of *Anisakis*, ingested with a meal of infected raw fish, causes acute, severe abdominal pain. Double-contrast barium studies can be diagnostic; threadlike filling defects are associated with a mound of mucosal edema at the site of larval penetrations of gastric wall.¹⁶⁰ Endoscopic removal of the larvae results in resolution of abdominal pain.

Although giardiasis may occur in the setting of dysgammaglobulinemia, immunocompetent children can be infected if the water source is contaminated. Duodenal spasm, thickening of the mucosa, and increased intraluminal fluid are characteristic but nonspecific radiologic features of infection.¹⁶¹ *Strongyloides* also affects duodenal mucosa and provokes an inflammatory response. Chronic disease results in a fixed, narrowed, and featureless duodenum.¹⁶²

The location and type of injury that occurs secondary to ingestion of caustic substances are largely dependent on the pH of the ingested agent. High-pH, alkaline agents are more viscous, leading to relatively prolonged contact time with the esophagus (see Chapter 115). On the other hand, low-pH, acidic agents are less viscous, resulting in rapid transit through the esophagus into the stomach, with predilection for pooling in the antrum

Figure 116-23 Ascariasis. A 5-year-old girl from Puerto Rico had a 2-month history of abdominal pain. Diarrhea was accompanied by vomiting, and the vomitus contained worms. Notice the unusual gas pattern in the middle duodenum and jejunum.

and pylorus.¹⁶³ Because the type of necrosis induced by acids is characterized by coagulation rather than by liquefaction, the wall penetration and subsequent perforation that are seen with alkali agents in the esophagus are less frequently encountered with acid injury in the stomach.¹⁶³ More often, mucosa of the stomach, and sometimes the duodenum, becomes thickened or ulcerated, resulting in gastric outlet obstruction, which is the most commonly reported complication of acid ingestion (Fig. 116-24).¹⁶³⁻¹⁶⁵ Radiology is useful in the follow-up of prior caustic injury because scarring takes weeks to months to evolve.

Figure 116-24 Gastritis from caustic ingestion. Marked antral narrowing with fold thickening and ulceration (arrow) are seen in this 7-year-old boy, who accidentally swallowed sulfuric acid.

Stenosis and contraction of the stomach and rigidity of the duodenal loop are characteristic of prior caustic ingestion.¹⁶⁶

GASTRIC OR DUODENAL DISTENTION

Gaseous distention of the stomach is seen in several disorders peculiar to the pediatric population. Many children swallow air when crying or nervous. There is overt aerophagia in some groups of youngsters with neuromuscular impairment and developmental delay.^{167,168} Gastric distention with air occurs with tracheoesophageal fistula, with or without esophageal atresia, or after an endotracheal tube is inadvertently placed in the esophagus. Diabetes mellitus and prior starvation are causes of gastric dilation that probably results from atony.

Distention of the stomach predisposes it to volvulus. Volvulus is also associated with deficient mesenteric and ligamentous attachments and diaphragmatic defects.^{167,168} Mesenteroaxial volvulus is a twist along an axis joining the lesser and greater curvature of the stomach. It has a characteristic appearance on plain radiographs.¹⁴⁷ Organoaxial volvulus is a twist along the gastric axis.¹⁶⁹ Intrathoracic gastric volvulus may accompany a large congenital hiatal or diaphragmatic hernia (Fig. 116-25).^{170,171}

SMA syndrome is obstructive compression of the third and fourth parts of the duodenum by the SMA and the root of the mesentery.¹⁷²⁻¹⁷⁵ It may follow surgery and casting for correction of scoliosis (i.e., cast syndrome) or may occur after severe weight loss. Plain radiographs and upper gastrointestinal series show distention of the stomach and proximal duodenum and a sharp cutoff in the midtransverse portion of the duodenum. Feeding in the prone position, hyperalimentation, or nasojejunal feeding alleviates the symptoms in most patients, and operative treatment is rarely necessary.¹⁷²⁻¹⁷⁵

Idiopathic megaduodenum is part of the spectrum of chronic intestinal pseudo-obstruction, and it may occur sporadically or in families.^{176,177} The condition is caused by disease of the smooth muscle, abnormal extrinsic or intrinsic nerves, or alteration of the neuroendocrine environment. Dilation of sections

Figure 116-25 Gastric volvulus. **A.** Abdominal radiograph shows congenital left diaphragmatic hernia. **B.** Upper gastrointestinal examination shows gastric volvulus associated with the herniated stomach. Arrow identifies the gastroesophageal junction. There are both organoaxial, with greater curvature superior to lesser curvature, and mesenteroaxial, with duodenum (arrowhead) to the left of the stomach, components to the volvulus.

of the gastrointestinal tract without anatomic obstruction is characteristic. Bacterial overgrowth and diarrhea are common problems. Secondary megaduodenum from diabetes, scleroderma, and amyloidosis are always mentioned in differential diagnoses, but these disorders are rare in pediatric patients.

Radiographically demonstrable abnormalities of the duodenum are common in cystic fibrosis and most prevalent in the second portion of the duodenum.^{178,179} Thickened mucosal

folds, nodular mucosa, and increased intraluminal fluid are typical features. These findings have been attributed to hyperplasia of the Brunner glands, tenacious mucus, mucosal edema, or inappropriate contraction of the muscularis mucosae.¹⁸⁰ Because an ulcer is difficult to detect on this background of abnormal mucosa radiographically, endoscopy is recommended in patients with cystic fibrosis who have symptoms of peptic ulcer disease.¹⁸⁰

Henoch-Schönlein Purpura

Clinical Findings

Imaging Findings

Meckel's Diverticulum**CLINICAL FINDINGS**

Meckel's diverticulum is a common congenital abnormality of the gastrointestinal tract that can produce varied complications and therefore diverse clinical manifestations. It is the most frequent in a spectrum of abnormalities that occur in the small bowel secondary to failed regression in early fetal life of the omphalomesenteric (vitelline) duct, the tract through which the primitive midgut communicates with the yolk sac. Incomplete resorption of the duct can produce abnormalities anywhere along its course between the ileum and the umbilicus, which in addition to Meckel's diverticulum include omphalomesenteric or mesodiverticular bands, vitelline fistula, omphalomesenteric cyst, and umbilical polyps (Fig. 117-1).¹⁻⁹

Meckel's diverticulum is a result of the patency of the ileal end and closure of the umbilical end of the omphalomesenteric duct and is a true diverticulum, composed of all bowel layers. Unlike alimentary duplications and most other bowel diverticula, Meckel's diverticulum arises from the antimesenteric border of the bowel and has a separate blood supply, the vitelointestinal artery.^{5,8} According to the "rule of 2's," Meckel's diverticulum has an incidence of approximately 2%, arises in the ileum within 2 feet of the ileocecal valve, and becomes clinically symptomatic by the age of 2 years.^{8,10}

Clinical symptoms secondary to complications of Meckel's diverticulum are varied and occur in approximately 4% of patients with Meckel's diverticulum. The most common complications are rectal hemorrhage and intussusception.^{1-5,8}

Painless lower gastrointestinal bleeding is a major complication of the approximately 20% to 55% of Meckel's diverticula that contain acid-secreting ectopic gastric mucosa and is more frequent in children than in adults.^{1,3} The small bowel adjacent to the ectopic gastric mucosa becomes ulcerated from exposure to the acid, resulting in hemorrhage. Ileoileal and ileocolic intussusceptions result when Meckel's diverticulum serves as a lead point, and an irreducible intussusception should raise suspicion for Meckel's diverticulum.^{1,2,4-6,8,10} Other

less common complications of Meckel's diverticulum include small bowel obstruction from volvulus or hernia around an associated omphalomesenteric band; bowel perforation; diverticulitis or inflammation of the diverticulum itself; and Littre hernia, which is an inguinal hernia containing Meckel's diverticulum.^{1-2,8-10}

A specific form of Meckel's diverticulum is giant Meckel's diverticulum, which tends to be larger than the average size of 2×3 cm and is long with a narrow neck.¹¹ It can serve as a lead point for focal volvulus or may undergo torsion at its base.^{11,12} Stasis in enormous Meckel's diverticula may lead to bacterial overgrowth, resulting in malabsorption.

IMAGING FINDINGS

Plain abdominal radiographs usually have normal findings but may show obstruction if the diverticulum is complicated by intussusception. Meckel's diverticulum rarely fills on routine barium studies, possibly because of small size or blockage of the lumen with ingested debris, but it may opacify with the higher pressures of enteroclysis.^{8,13} Difficulty in detection is compounded by overlying bowel loops that may obscure the diverticulum unless they are displaced with compression. A mucosal triangular plateau or a triradiate fold pattern in the right lower quadrant has been described in small bowel examinations in patients with Meckel's diverticulum.¹³ Air-filled giant Meckel's diverticula may fill with contrast medium on delayed studies (Fig. 117-2).¹² Children with small bowel hernia or volvulus around an omphalomesenteric band often show nonspecific findings of lower small bowel obstruction (Fig. 117-3).

Advanced imaging including computed tomography (CT) and ultrasound is routinely used to study children who present with symptoms of an acute abdomen, especially right lower quadrant pain. Meckel's diverticulum itself as well as secondary complications such as intussusceptions can be detected (Fig. 117-4). On sonography, inflamed Meckel's diverticulum can appear as a cystic or tubular structure with thickened walls, sometimes displaying the characteristic alternating hyperechoic and hypoechoic bands of intestinal wall.⁴⁻⁷ Doppler and color Doppler sonography may demonstrate the inflammatory changes more clearly.⁴⁻⁷ By CT or magnetic resonance (MR) enterography, the inflamed diverticulum may appear as an air-, fluid- or contrast-filled blind-ending pouch with thickened walls in the right lower quadrant with inflammatory changes in the adjacent mesentery.^{3-6,14} Inverted Meckel's diverticulum, often the lead point of an intussusception, may also be seen as a filling defect in the opacified lumen.^{15,16}

Dilated and inflamed Meckel's diverticulum can resemble the dilated and inflamed appendix in appendicitis by sonography and CT. Clinical symptoms of right lower quadrant pain and fever also overlap in the two entities, and identification of the normal appendix in cases of suspected Meckel's diverticulum is recommended to aid in differentiation between the

two.^{8,10,14} An ileal duplication cyst may mimic Meckel's diverticulum; Meckel's diverticulum is distinguishable from an ileal duplication cyst by its thicker, more irregular wall and the presence of peristalsis.^{8,14}

Technetium Tc 99m pertechnetate nuclear scintigraphy is the most widely used method for diagnosis of bleeding Meckel's diverticula, and it has a sensitivity of 85%.^{4,5,8,17,18} The intravenously injected isotope localizes in the right lower quadrant of the abdomen within the ectopic gastric mucosa, with rate and pattern of activity mirroring that of gastric mucosa in the stomach (Fig. 117-5). Administration of pentagastrin before scintigraphy may be used to stimulate diverticular gastric mucosal uptake and thereby enhance sensitivity of detection if the result of a prior study has been negative or equivocal and Meckel's diverticulum is still strongly suspected.¹⁸

Figure 117-1 Abnormalities of regression of the omphalomesenteric duct. **A.** Umbilical polyp. **B.** Mesodiverticular or omphalomesenteric band. **C.** Patent omphalomesenteric duct or vitelline fistula. **D.** Vitelline cyst. **E.** Meckel's diverticulum.

False-negative study results can occur when residual gastrointestinal barium absorbs the emitted gamma rays, when profound ulceration or infarction has destroyed the gastric mucosa within the diverticulum, or when the isotope is incorrectly interpreted as being within the genitourinary tract. Lateral

Figure 117-2 Giant Meckel's diverticulum. The radiograph obtained after barium enema demonstrates residual contrast material within the colon and several small bowel loops. The large, rounded gas collection in the midabdomen, causing proximal small bowel obstruction, is a giant Meckel diverticulum.

Figure 117-3 Omphalomesenteric band. **A.** Multiple, dilated small bowel loops suggest a low obstruction on the plain abdominal radiograph of an infant. **B.** The colon was normal, except that the right colon was displaced from the lateral abdominal wall, and it was impossible to distend the cecum. At surgery, small bowel that had herniated beneath the omphalomesenteric duct was found to be entrapped.

Figure 117-4 Meckel's diverticulum: ultrasound and CT. **A.** An ileocolic intussusception (arrow) is seen within fluid-filled colon by sonography. **B.** A thick-walled, fluid-filled cyst within the intussusceptum (arrow) represents inflamed Meckel's diverticulum. **C.** Corresponding CT image shows circumferential wall thickening of the fluid-filled, inflamed cyst in the right lower quadrant (arrow).

scans of the abdomen are performed routinely to minimize the last error.⁸ False-positive study results can also occur, but they are easier to recognize. Ectopic gastric mucosa in alimentary cysts is responsible for most of the false-positive results. Inflammatory processes may rarely localize the isotope, despite the absence of gastric mucosa.

Intestinal Lymphangiectasia

CLINICAL FINDINGS

Congenital and acquired disorders of the small bowel lymphatics can produce protein loss, diarrhea, and decreased immunoglobulin levels.¹⁹ Histologic changes include diffuse or focal dilation of lymphatics in all bowel layers that may be accompanied by villous changes and infiltration of the mucosa by inflammatory cells.¹⁹⁻²² Leakage of protein-rich lymphatic fluid from the dilated lymphatic channels into the gastrointestinal tract results in protein-losing enteropathy. Congenital lymphatic structural malformation is termed primary intestinal lymphangiectasia (Waldmann's disease) and typically is manifested before 3 years of age. Common symptoms include bilateral lower extremity edema and gastrointestinal complaints such as diarrhea, abdominal pain, nausea, and vomiting.²²

Because of the protein loss through the small bowel, the child may fail to thrive. Similar loss of lymph cells may produce lymphopenia. Definitive diagnosis of primary lymphangiectasia is made by endoscopy and intestinal biopsy.²³ Elevated levels of α_1 -antitrypsin in a 24-hour stool sample are indicative of protein-losing enteropathy and support the diagnosis.^{22,23}

When dilation of lymphatic channels is secondary to venous obstruction or elevated venous pressure, the disorder is termed secondary lymphangiectasia. Conditions known to cause secondary lymphangiectasia include inflammatory bowel disease, sarcoidosis, lymphoma, congestive heart failure, and constrictive pericarditis.²² Secondary lymphangiectasia is an uncommon but well-recognized complication in children who have undergone a Fontan procedure for complex congenital heart disease. Intestinal lymphangiectasia has long been recognized as part of the Noonan, Turner, Klippel-Trénaunay, and von Recklinghausen syndromes.²² Hennekam syndrome, an autosomal recessive disorder with mild to moderate mental retardation, peculiar facies, and ear defects, is also associated with lymphangiectasia.²⁴⁻²⁶

IMAGING FINDINGS

Small bowel series show thickening of the valvulae conniventes, nodularity of the mucosa, and excess secretions if

Figure 117-5 Meckel's diverticulum: nuclear scintigraphy. Technetium pertechnetate has passed from the stomach into the proximal small bowel. A small region of abnormal and persistent activity in the right lower quadrant (arrow) represents isotope localizing within ectopic gastric mucosa within Meckel's diverticulum.

there is malabsorption.¹⁹ The caliber of the gut is normal. Barium enema examination may show thickening of affected colonic folds.

Sonography and CT can also demonstrate the nonspecific findings of ascites, dilated lymphatics, and thickened bowel walls and mesentery.^{23,27-29} The last changes may be primary or result from the hypoproteinemia caused by this protein-losing enteropathy.

Functional imaging with human serum albumin nuclear medicine scintigraphy plays an important role in the work-up of suspected intestinal lymphangiectasia and has the advantage over α_1 -antitrypsin stool sampling of the ability not only to confirm the presence of the protein loss from the gastrointestinal tract but also to localize the anatomic site of protein leakage. In this diagnostic procedure, ^{99m}Tc -labeled human serum albumin is injected intravenously, and periodic images of the abdomen are obtained during a 24-hour period in search of abnormal radiotracer activity seeping in the bowel. Other radiopharmaceuticals used for this purpose include ^{99m}Tc -methylene diphosphonate and ^{99m}Tc -dextran.^{22,23,28}

Henoch-Schönlein Purpura

CLINICAL FINDINGS

Henoch-Schönlein purpura is the most common systemic vasculitis of childhood, typically involving the small bowel and kidney, and is associated with a distinctive rash.^{30,31} Henoch-Schönlein purpura spares the very young and is most common

in children between the ages of 3 and 10 years, occurring with a slight male predominance. As many as 30% of affected patients may be older than 20 years.^{30,31} It occurs more often in the winter than in other seasons.

Small bowel involvement in Henoch-Schönlein purpura is characterized by ischemia or hemorrhage into the bowel wall. The subsequent abdominal pain may be intense, simulating that of a surgical abdomen.³²⁻³⁶ Surgery may be needed in the 3% to 5% of children with Henoch-Schönlein purpura who develop complications, including bowel perforation and irreducible intussusception.³²⁻³⁴ Ileoileal intussusception occurs as often as the more common ileocolic intussusception. When the intussusception involves the small bowel alone, it frequently reduces spontaneously despite the underlying disease process. Gastrointestinal bleeding, which is less common in older patients, occurs in about half of the pediatric patients but is unlikely to require transfusion. Most children recover completely without residua of the acute process.

Renal disease usually is manifested as hematuria, whereas a significant decline in renal function is uncommon. Renal biopsy may document glomerulonephritis or changes of immunoglobulin A nephritis. The associated rash may evolve from a urticarial to a maculopapular rash to become the classically described palpable purpuric lesions. The skin lesions are most prominent over the buttocks and lower extremities. Biopsy of the skin lesions shows granulocytes around arterioles and venules.³¹ Brain involvement is less common but may take many forms, including seizures, blindness, and headache.³⁷ Genitourinary involvement is uncommon but may produce testicular or epididymal pain and simulate testicular torsion or epididymo-orchitis.³⁸ Arthralgias typically occur in a few large joints and can precede the skin lesions.

IMAGING FINDINGS

Plain radiographs of the abdomen usually have normal findings unless there has been perforation, intussusception with small bowel obstruction, or sufficient bowel wall thickening to produce thumbprinting of segments distended with air.³⁴ Studies of the upper gastrointestinal tract with contrast material show mucosal thickening and submucosal edema that tend to be localized (Fig. 117-6).³⁴ Obstruction or intussusception may be detected. Contrast enemas performed to reduce an ileocolic intussusception are well tolerated but usually are unsuccessful.³⁹

Sonography demonstrates mural thickening and sometimes fluid distention of affected bowel segments, usually jejunum or ileum (Fig. 117-7), which is often distended with fluid.^{34,39,40} Sonography is also useful in excluding associated abdominal processes such as intussusception. Sonography or scintigraphy has been used to evaluate those who develop acute scrotal pain or tenderness.^{38,41,42}

Diagnostic features of Henoch-Schönlein purpura, including bowel wall thickening and wall enhancement, are well demonstrated by advanced dedicated bowel imaging techniques such as CT and MR enterography performed with intravenous administration of contrast material as well as an oral contrast agent to achieve bowel distention (Fig. 117-8).^{35,43-45} Similar bowel abnormalities can be seen in a variety of other disorders, including graft-versus-host disease, ischemic or infectious enteritis, and inflammatory bowel disease.^{35,43,46,47}

Figure 117-6 Henoch-Schönlein purpura: small bowel examination. The valvulae are thickened in the jejunum. Contrast medium is diluted as it passes into more distal, fluid-filled loops.

contrast barium enema studies and may be seen in 50% to 70% of such examinations in children (Fig. 118-1).^{1,2} Normal follicles are 2 mm in diameter, are uniform in size, and often have central umbilications. They can simulate familial polyposis in the way they carpet the colon. Follicles larger than 2 to 3 mm are associated with nodular lymphoid hyperplasia, which occurs in response to a number of immunologic, infectious, inflammatory, or allergic stimuli.^{3,4}

Anterior Anus

The anterior anus, an organic cause of constipation, is seen in some children who were previously said to have psychogenic constipation or suspected of having Hirschsprung's disease (HD).^{5,6} The anterior anus may be a mild variant of imperforate anus with perineal fistula.^{5,6}

The amount of anal displacement may be minimal and difficult to appreciate by physical examination. The external changes may be more difficult to discern in boys than in girls. The position of the anus does not by itself determine the degree of dysfunction.⁷ Affected children may have an abnormal evacuation history from birth or may evacuate normally for several months. A long interval between bowel movements, straining with defecation, and fecal soiling are also common complaints.^{5,6}

Treatment is surgical. The anorectal canal and internal anal sphincter are mobilized, and a neorectum is created in a normal location. The surgery has a low complication rate and allows development of nearly normal evacuation patterns.^{5,7-9}

The differential diagnosis of anterior anus includes HD, neurologic constipation, and psychogenic constipation. These disorders can usually be excluded on the basis of physical examination, spine radiographs, rectal manometry, and rectal biopsy.

RADIOLOGIC FINDINGS

Conventional radiographs are used to evaluate the amount of stool present and to detect spinal anomalies. If a large amount of stool obscures the sacrum, a lateral spine radiograph may be necessary to exclude sacral deformities that may be associated with neurogenic rectal dysfunction.

On barium enema examination, the lateral rectal view is key in diagnosis. In children with anterior anus, there is a deep posterior recess or shelf behind the rectal catheter (Fig. 118-2). The rectum descends below the last turn of the colon as it passes anteriorly to become the anus. Postevacuation radiographs, with the rectal tube removed, show that the anus is more anterior than usual and lies at an angle to the posterior rectal shelf, which is in a normal position a few millimeters anterior to the sacrum.

Lymphoid Follicular Pattern and Lymphoid Hyperplasia

Lymphoid follicles are a normal feature of the gastrointestinal tract and are much more prominent in children than in adults. The lymphoid follicular pattern is best appreciated on double-

Figure 118-1 Lymphoid follicular pattern. Fine nodules of similar size are seen throughout the colon on this double-contrast barium enema study.

Hirschsprung's Disease

PATHOLOGIC FINDINGS

HD is characterized by absence of ganglion cells in Auerbach's and Meissner's plexus in the affected bowel.¹⁰ The process is probably caused by arrest of the usual craniocaudal migration of primitive neuroblasts, which in some children is associated with other abnormalities of the neural crest. Research indicates that children with central hypoventilation syndrome have an increased incidence of HD.¹¹

The involved segment is of variable length and is always distal. Approximately 85% of cases are limited to the descending colon and distal segments; 55% of all cases involve the rectosigmoid colon and distal segments.^{10,12} Total colonic aganglionosis, with or without small bowel involvement, is seen in 8% of affected children.^{10,12-14} Extensive aganglionosis is a rare, usually lethal variant in which the entire small bowel and even the stomach lack normal ganglion cells.¹⁴ Zonal aganglionosis is rare and may be an acquired lesion or have a different embryologic basis.

CLINICAL FINDINGS

Two thirds to three fourths of children with classic HD are male. Boys and girls are equally affected with total colonic aganglionosis. HD is the most common cause of neonatal obstruction of the colon, and more than 70% of cases are diagnosed in this period.^{10,12} Neonates present with delayed passage of meconium, abdominal distention, or vomiting. Delay in diagnosis

Figure 118-2 Anterior anus. Barium enema study shows that the rectum is capacious and contains much fecal debris. A deep posterior segment of the rectum (arrows) far behind the anus is identified by the catheter tip.

can lead to bowel perforation or potentially fatal enterocolitis.¹⁵⁻¹⁷ About 5% of children with HD die of enterocolitis, usually within the first 3 months of life, and about 10% of children with HD develop enterocolitis before surgery. Pseudomembranous colitis may also occur in these children, even without recent exposure to antibiotics, and it can lead to perforation of the appendix and proximal colon in 5% of cases.¹⁸ Because pseudomembranous colitis is treatable, it may be useful to obtain stool cultures in children with HD and "typical" colitis.¹⁷

Older children with undiagnosed HD usually have an abnormal neonatal stooling history and unremitting constipation.^{19,20} On occasion, the diagnosis is delayed until the second and third decades of life, leading to chronic constipation, chronic laxative abuse, and colonic distention, which predispose the colon to volvulus.

The clinical history and physical examination findings usually are specific. In contrast to children with psychogenic constipation, whose symptoms begin at the time of toilet training, children with HD have an abnormal stooling history as neonates and rarely have fecal soiling. On physical examination, the rectal ampulla is full in children with psychogenic constipation and empty in those with HD.

Distention of the rectum fails to produce normal reflex relaxation of the internal sphincter in children with HD.²¹ Rectal manometry may be performed if the diagnosis remains uncertain, particularly in children with a normal barium enema result who do not respond to medical therapy for

constipation.²¹ Rectal manometry may give equivocal or incorrect results in approximately 18% of those younger than 1 month and in 10% older than this.²¹

Suction biopsy of the rectal mucosa excludes the diagnosis of HD by histologic demonstration of ganglion cells. Full-thickness biopsy of the rectum is reserved for problem situations, such as when the radiologic pattern is atypical or when the mucosal biopsy is inconclusive.²²

In most children, HD is an isolated finding, but there is an increased incidence of this disorder among children with trisomy 21, Waardenburg's syndrome, Smith-Lemli-Opitz syndrome, and several other syndromes. In some families, HD appears to be genetically transmitted.²³⁻²⁵ Genetic factors may be present in up to 20% of patients, and a dominant inheritance pattern has been identified in several families. Multiple genes have been implicated in HD, and many mutations have been observed with neurodevelopmental genes.²⁶

There is an increased incidence of malrotation in children with HD.²⁷ In utero, this malrotation may lead to volvulus and ischemia and contribute to the increased incidence of intestinal atresia in children with HD.^{27,28} The association of HD with intestinal atresia also suggests that the ischemic event that produced the atresia might have interfered with the craniocaudal migration of neuroblasts.

THERAPY

Initial treatment of HD is directed toward decompressing the colon to prevent enterocolitis. Although this can be achieved with saline solution enemas, a one-stage neonatal repair may be done. This consists of a transanal endorectal pull-through without or with laparoscopic assistance by intraoperative pathologic guidance to define the true transition zone. In children with markedly dilated colon or those weighing less than 2 kg, a colostomy is performed. Definitive or corrective surgery is usually delayed several months. All operations (i.e., Swenson, Soave, and Duhamel procedures) attempt to restore normal function by removing or bypassing the aganglionic segment.^{10,12} Postoperative complications include leakage at the anastomosis, continued obstruction, and, rarely, development of secondary aganglionosis in a previously normal segment.

When HD is diagnosed in an older child, a colostomy is performed before corrective surgery to enable the enlarged colon to normalize in caliber. This makes later surgery easier. Children with total colonic aganglionosis undergo ileostomy under histologic intraoperative guidance to enable placement of the ileostomy in a segment that contains ganglion cells. Later, these children undergo total colectomy and ileoanal endorectal pull-through.¹⁹

RADIOLOGIC FINDINGS

Early diagnosis of HD can be lifesaving. Unfortunately, radiologic diagnosis is more difficult in the neonatal period than in later life. Conventional radiographs show changes of distal bowel obstruction. Rarely, calcifications may be present in bowel lumen.²⁹

Contrast enema examination is performed for diagnosis and to exclude other causes of distal obstruction, such as meconium plug, small left colon syndrome, and ileal atresia. When HD is suspected, a small-caliber enema tip may be used to avoid dilating the rectum.

The enema is begun with the infant or child in the left lateral decubitus position to improve visualization of the segments most likely to be abnormal: the rectum and the rectosigmoid (Fig. 118-3). In infants, a funnel- or cone-shaped appearance suggests HD (Fig. 118-4). Despite reports that delayed abdomen radiographs demonstrating retained barium are valuable in confirming the diagnosis, filling of the colon proximal to an abnormal configuration is not recommended in case the barium becomes impacted. A lateral radiograph of the rectum obtained after the enema tip has been removed may be key to appreciating the abnormally small rectal vault and demonstrating the abnormal rectosigmoid index.^{30,31} A crinkled appearance of the distal colon, the corrugated rectum, is another finding of

Figure 118-3 Hirschsprung's disease. On this lateral view from a barium enema study, the rectum is smaller than the sigmoid colon. The corrugated appearance of the rectum has also been described in Hirschsprung's disease.

Figure 118-4 Hirschsprung's disease. The diagram (lateral view) depicts the varied appearance of the transition zone in the rectum in Hirschsprung's disease. **A.** In the very young, the transition zone may be cone shaped, with the caliber imperceptibly decreasing as it goes from the sigmoid colon to the rectum. **B** and **C.** A discrete change in caliber is more typical, with the radiologic transition zone more clearly defined in **C.**

Figure 118-5 Total colonic Hirschsprung's disease. Frontal (A) and lateral (B) views from a barium enema study show that the rectum is larger than the more proximal colon. Intense spasm from colitis prevents colonic distention. Spiculation and mucosal ulcerations are present throughout, except in the rectum.

aganglionosis and may become more apparent after the catheter tip is removed.

In the neonate with total colonic aganglionosis, the colon may fill easily with rapid reflux into the small bowel, with a transition zone demonstrated between normal and dilated bowel in the ileum and with loss of the normal colonic redundancy. The abnormal colon may instead appear normal, have a meconium plug, or be a microcolon.^{32,33}

HD-induced colitis produces a spastic, difficult to distend colon with a spiculated or saw-toothed mucosa (Fig. 118-5). Active colitis produces rapid expulsion of barium, which accounts for false-negative, delayed postevacuation radiographs in children with HD.

In the older child with a history of constipation, the contrast enema is performed in an unprepared colon because decompression of the dilated colon and dilation of the rectum may decrease the abrupt changes that produce the classic transition zone. *Transition zone* is the term applied to the region in which there is a perceptible change in caliber, with the dilated normal colon above and the narrowed aganglionic colon below. The dilated segment may contain aganglionic bowel because the innervated enlarged colon pushes its contents distally and dilates the abnormal segment.^{34,35} Pathologic confirmation of the true transition zone is always obtained before palliative or corrective surgery is performed.

When barium enema examination shows a dilated rectum and sigmoid colon, classic HD has been excluded; the colon above is filled to see the extent of colonic distention and to evaluate bowel rotation. Parents should be instructed in ways to enhance the passage of barium afterward. When the child undergoes a bypass procedure as the initial surgical therapy, the distal segment is usually studied with contrast enema before gastrointestinal continuity is reestablished. It may appear poorly distensible and rigid with mucosal thickening, nodularity, and

polypoid lymphoid hyperplasia.³⁶ Redundancy, if present, is a result of prior dilation of the ganglionic portion of this segment.

After definitive corrective surgery, there is no routine time or indication for radiologic study. If the child is septic in the immediate postoperative period, gentle instillation of water-soluble contrast material into the rectum through a small catheter can demonstrate an anastomotic leak. Alternatively, contrast-enhanced computed tomography (CT) of the pelvis may demonstrate the suspected collection or abscess and better define its extent and secondary complications.

Inflammatory Bowel Disease

The pathology, epidemiology, and radiographic findings in ulcerative and Crohn's colitis are discussed in Chapter 57. This short discussion focuses on a few aspects of ulcerative colitis in the child. Pediatric Crohn's disease is presented in Chapter 116.

Ulcerative colitis is rare during the first and uncommon in the second decade of life. The symptoms of diarrhea with blood or mucus, abdominal pain, and fever suggest a juvenile polyp, Meckel's diverticulum, or infectious or allergic colitis. Anemia and weight loss may also develop.³⁷⁻⁴⁰

The radiographic findings in children with ulcerative colitis are identical to those in adults. Toxic megacolon, however, occurs much less commonly in children.

Other Colitides and Causes of Diarrhea

Persistent bloody or watery diarrhea is unusual in children and is a cause for concern because it may lead to electrolyte abnormalities, protein and weight loss, and irritation of the buttocks. Viral, bacterial, or parasitic processes are frequently the source

of the problem.⁴¹⁻⁴³ In up to 28% of children, the cause of the diarrhea may elude diagnosis despite numerous diagnostic tests. Celiac disease, usually considered to be a small bowel disorder, may be the most common noninfectious cause of diarrhea. Diagnosis is based on response to a gluten-free diet and results of a small bowel biopsy.⁴⁴

Milk allergy and lactose intolerance can cause diarrhea in children.^{45,46} The inability to digest lactose can cause diarrhea in the first year of life. Removal of the offending disaccharide results in remission of symptoms. The proteins in cow's milk and soy-based milk can damage the gastrointestinal mucosa in some children with allergy to these foods. Rectal biopsy may show diagnostic histologic changes. Barium enema examination may show nonspecific changes of colitis: narrowing, thumbprinting, and spasm. Although these changes usually involve the entire colon, segmental changes have been described. The small bowel may also be affected, producing thickening of the valvulae conniventes or narrowing of involved segments.

A rare cause of diarrhea in children is collagenous colitis.⁴⁷⁻⁴⁹ This colitis is associated with watery diarrhea and colicky pain. Microscopic analysis of biopsy specimens of mucosa is necessary for diagnosis. Widening of the collagen band of the basement membrane, few inflammatory cells, and edema of the lamina propria are observed. Symptoms usually respond to corticosteroids or sulfasalazine but may recur after the medications have been withdrawn.

Tumor is a rare cause of watery diarrhea. A few ganglioneuromas and ganglioneuromas secrete vasoactive intestinal polypeptide, which, as its name suggests, produces increased intestinal motility.⁵⁰ This disorder is often unsuspected, but the diagnosis is made when the conventional radiograph preceding barium enema reveals paravertebral mass or calcifications. Plasma levels of vasoactive intestinal polypeptide can be measured to confirm the diagnosis, and CT or sonography may be useful in delineating tumor size and tissue of origin. Removal of the tumor is followed by cessation of the diarrhea.

Kawasaki's disease may cause a variety of physical and physiologic changes: abdominal pain, serum abnormalities indicative of liver disease, frank organ necrosis, and atypical colitis simulating ischemic colitis.⁵¹

Hemolytic Uremic Syndrome

CLINICAL FINDINGS

Hemolytic uremic syndrome (HUS) is a pathologic entity with two different groups of affected patients.⁵²⁻⁵⁴ In some, an infection with a specific *Escherichia coli* is associated with the development of HUS. In others, especially those with relapses of the disease, there may be a genetic component. Both groups suffer an acute microangiopathic hemolytic anemia, oliguric renal failure, and thrombocytopenia.⁵²⁻⁵⁴ HUS usually occurs in toddlers and children between 2 and 10 years old, who present with an influenza-like illness, gastroenteritis, and bloody diarrhea that precede the more striking renal and hematologic manifestations by several days or weeks. The gastrointestinal manifestations of the prodromal period are protean, requiring differentiation from ulcerative colitis, pseudomembranous colitis, granulomatous colitis, shigellosis, salmonellosis, intussusception, and causes of an acute surgical abdomen.⁵²⁻⁵⁶ Diagnosis is often delayed until anemia, thrombocytopenia, or renal failure appears. Urinalysis provides vital information because

most patients have proteinuria, hemoglobinuria, or hematuria (microscopic or gross) early in the course of the disease. Those who present without diarrhea have a worse prognosis for renal disease than those who have diarrhea at presentation.⁵⁷ The peripheral blood smear is also suggestive when schistocytes and burr cells are present. Patients may experience central nervous system symptoms, sometimes associated with abnormal findings on CT and magnetic resonance (MR) examinations.⁵⁸

The vigorous fluid therapy given to children with active peritoneal signs typical of HUS may result in overhydration and cause peripheral and pulmonary edema when acute renal failure develops. Prompt diagnosis may avert an unwarranted laparotomy and contribute to the proper management of fluid needs. Dialysis is necessary until renal function resumes.

Most patients recover without sequelae. Death, more frequent in children with anuria, is attributable to the manner in which the thrombotic process affects organs other than the kidneys.

RADIOLOGIC FINDINGS

Conventional radiographs often have abnormal findings but are nondiagnostic. A disordered bowel gas pattern and thickening or thumbprinting of affected bowel loops may be observed.⁵⁹

The colon may demonstrate spasm, thumbprinting, ulceration, straightening, and narrowing of edematous segments (Fig. 118-6) on barium enema examination. Later, strictures may form.

Sonography is useful in excluding causes of a surgical abdomen and in showing changes that suggest the diagnosis:

Figure 118-6 Hemolytic uremic syndrome. Spasm and ulceration are present in the descending colon, and mild thumbprinting deforms the transverse colon on this barium enema study.

peritoneal fluid, bowel wall thickening, and increased echogenicity of the renal parenchyma.⁶⁰ During periods of oliguria or anuria, there are profound abnormalities of systolic and diastolic blood flow on Doppler studies. A return of normal blood flow heralds impending diuresis, useful information in children undergoing dialysis.⁶⁰

Appendicitis

CLINICAL FINDINGS

The most common indication for emergency laparotomy in children is an inflamed or ruptured appendix. The diagnosis is based on symptoms (e.g., abdominal pain, vomiting, low-grade fever), signs (e.g., pain on palpation of the right lower quadrant, rebound tenderness), and laboratory data (e.g., low-grade leukocytosis, absence of urinary tract infection). When the presentation is classic, surgery is usually performed without radiologic studies. Imaging is performed in those whose atypical presentation suggests the possibility of other, even nonsurgical, diagnoses. Sonography has demonstrated that alternative diagnoses may be established in up to 25% of the patients with suspected appendicitis.⁶¹

Infectious enteritis, Crohn's disease, mesenteric lymphadenitis, intussusception, acute pyelonephritis, omental infarction, and Meckel's diverticulitis are other possibilities that can be suggested with sonography or CT in the setting of suspected appendicitis. In teenage girls, gynecologic conditions, including pelvic inflammatory disease, ovarian cyst, hematometrocolpos, ovarian torsion, and pregnancy, may be diagnosed.⁶¹

Rupture or perforation occurs more commonly in children than in adults.⁶²⁻⁶⁵ In pediatric patients who have had preoperative imaging studies, the perforation rate at surgery is as high as 50%.⁶⁶ After rupture, the abdominal symptoms may temporarily diminish, which obscures the diagnosis.

If rupture has occurred, the inflammation of the local soft tissues (e.g., bowel, omentum) is called a phlegmon. Phlegmon or periappendiceal abscess is reported in as many as 37% of children with acute appendicitis and is more common in those whose symptoms are of longer duration.⁶⁴ Phlegmon or periappendiceal abscess may be palpated as a right lower quadrant mass. A complete discussion of the diagnosis, treatment, and prognosis of appendiceal abscess is presented in Chapter 56.

RADIOLOGIC FINDINGS

The radiologic findings in children with appendicitis are identical to those in adults and are discussed in Chapter 56. Certain features of pediatric appendicitis should be considered. Appendicoliths are more common in children than in adults with appendicitis and, when present, are more likely to be associated with appendiceal rupture (Figs. 118-7 and 118-8).

The choice of imaging modality (and even whether to image) can be confusing. In some series, the use of preoperative imaging has increased the number of alternative, nonsurgical diagnoses and decreased the number of negative appendectomies, but others have opposite results and see a negative value in waiting for the study to be done. When cross-sectional imaging is indicated, sonography (Fig. 118-9) and CT (Figs. 118-10 and 118-11) have a specificity and sensitivity of more than 90%.⁶¹⁻⁶⁸ A normal appendix may be identified on sonography in up to 81% of children who do not have appendicitis (Fig. 118-12).⁶⁹

Figure 118-7 Appendicolith. A large, calcified appendicolith is seen below the right sacroiliac joint (arrow).

Figure 118-8 Appendiceal abscess. The terminal ileum is extrinsically compressed by and displaced around an appendiceal abscess on this small bowel series.

In thin children, ultrasound is a reasonable first-line choice. In heavier children or when ultrasound is not readily available, CT has been equally successful in diagnosing or excluding appendicitis or detecting alternative disease processes. MR imaging may be useful in the diagnosis of appendicitis when

Figure 118-9 Sonography of appendicitis. **A.** A dilated, incompressible appendix lies beneath the abdominal musculature on this longitudinal scan. **B.** Transverse scan of the right lower quadrant in a different child shows a widened appendix (arrows), suggesting appendicitis. The echogenic focus in the center causing distal shadowing is an appendicolith.

Figure 118-10 Appendicitis: abdomen radiograph and CT. **A.** Abdomen radiograph demonstrates a mild left lumbar scoliosis due to right psoas spasm. Several air-fluid levels are present in the lower quadrant bowel loops, a sign of focal ileus. **B.** CT demonstrates an appendicolith (arrows) in the dilated appendix.

ultrasonography is equivocal.⁷⁰ Controversy about how the CT study should be done (i.e., full abdomen and pelvis or focused to the abdomen and pelvis below the lower pole of the right kidney) and what is the proper preparation (i.e., rectal, oral, intravenous, or some combination of these) indicates that many techniques produce excellent diagnostic results.^{71,72}

An acutely ruptured appendix may be challenging to diagnose with sonography for a number of reasons. The decompressed appendix may have a diameter of less than 6 mm, an appendix may not be identified because of overlying bowel gas, and only questionable appendiceal remnants may be present after the inflammatory response develops in the surrounding tissues. Sonography and CT are helpful in differentiating

Yersinia enterocolitis (frequently associated with right lower quadrant pain) from appendicitis (Fig. 118-13). In addition to imaging of appendicitis, radiologists can percutaneously drain the appendiceal abscesses.⁷³

Typhlitis

Typhlitis, also known as neutropenic colitis because it may affect any segment of the colon, is acute inflammation of the cecum that occurs in immunosuppressed patients. It was originally described in children with immunosuppression due to treatment of acute myelogenous leukemia.⁷⁴ Typhlitis is seen in children and affects adults with many forms of immunosuppression; chemotherapy for treatment of malignant disease,

Figure 118-11 CT of appendiceal abscess. **A.** Moderate dilation of the right pelvicalyceal system and proximal ureter due to the mass effect of the right lower quadrant process is demonstrated on this retrograde pyelogram. **B.** CT reveals a complex mass (arrows), which compresses the right ureter.

Figure 118-12 Normal appendix. The blunt distal tip of the nontender, compressible appendix is superior to its proximal portion on this longitudinal scan.

organ and bone marrow transplantation, and AIDS are other significant risk factors.⁷⁴⁻⁷⁸

CLINICAL FINDINGS

Children with typhlitis present with right lower quadrant pain, neutropenia, fever, and peritoneal signs; they occasionally

present with an inflammatory mass and uncommonly with lower gastrointestinal hemorrhage. Perforation of the cecum may occur but is not necessarily lethal when it is treated immediately. Granulocyte transfusions, antibiotics, and surgical resection of affected bowel may stop the progress of the inflammation.^{77,78} Diagnostic delay may lead to perforation, sepsis, and death.

The differential diagnosis of typhlitis includes appendicitis clinically and pneumatosis intestinalis radiologically. A study of more than 450 children treated for hematologic malignant disease found that appendicitis and typhlitis occurred with almost equal frequency and demonstrated that CT studies were key in differentiating these diagnoses.⁷⁹

RADIOLOGIC FINDINGS

Conventional radiographs of patients with typhlitis may show an abnormal amount of bowel gas or a soft tissue mass in the right lower quadrant, ascites, or pneumatosis intestinalis. The pneumatosis may have a benign course. Free intraperitoneal air is a more ominous sign and indicates the need for surgery unless another source of the air is apparent.

Contrast enema has been reported to show changes in the appearance of the inflammatory process in the cecum but may lead to perforation. It is not recommended in patients with suspected typhlitis.

Angiography, rarely used for diagnosis, may demonstrate hyperemic changes of the mucosa, staining at sites of ulceration, and arteriovenous shunting.⁷⁵ Embolotherapy may be performed if bleeding is massive.

Sonography shows mural thickening of the cecum, ascending colon, and ileum.^{80,81} Color Doppler demonstrates increased transmural blood flow, in contrast to other processes, which may primarily affect the mucosa or instead be associated with diminished blood flow and ischemic change. Sonography is also useful in identifying abscesses and in excluding appendiceal inflammation. The success of CT in differentiating typhlitis

Figure 118-13 *Yersinia enterocolitis*. **A.** Several enlarged lymph nodes (cursors) are seen on this sagittal sonogram of a child whose appendix appeared normal. **B.** The enlarged lymph nodes produce an inhomogeneous mass in the right iliac fossa. The wall of the cecum (arrows) is thickened on the CT scan.

from other processes in this fragile population has fostered its increased use for this purpose.^{82,83}

Intussusception

Intussusception occurs when a proximal segment of bowel passes into the lumen of a more distal segment, and through peristalsis, it is propelled distally. The proximal segment is referred to as the intussusceptum, and the distal segment is called the intussusciens. Intussusceptions are named by the segments involved. The most common form (70%-90%) is ileocolic, in which the ileum is prolapsed into the colon for a variable distance. Less common types of intussusceptions are ileoileocolic, ileoileal, and jejunoileal.

Despite a seasonal variation in the incidence, which suggests a predisposing viral agent, most children with intussusception have no prodrome or discernible cause. Only 3% to 10% of children have an intrinsic bowel abnormality that serves as the lead point for the intussusception: duplication, hemangioma, polyp, Meckel's diverticulum, or lymphoma.⁸⁴⁻⁸⁶ Intussusception is a known but rare complication of surgery.⁸⁷ Most intussusceptions occur in children between 3 months and 3 years old, with a 2:1 male predominance. Almost one third of children who develop an intussusception outside this age range have a pathologic lead point.⁸⁴⁻⁸⁶ Nevertheless, radiologic reduction of the intussusception should be attempted in older children because most do not have a lead point and can therefore avoid surgery.

CLINICAL FINDINGS

Children with intussusception present with colicky abdominal pain. The stools may test positive for occult blood or have the classic but infrequent currant jelly appearance. Vomiting, diarrhea, and other gastrointestinal symptoms occur in more than 90% of cases. An abdominal mass may be palpated in slightly more than half of the affected children. A few children are lethargic or dehydrated. In neonates, vomiting is usually the most striking clinical finding. Rectal bleeding is also more common in the neonate with intussusception than in the older child and may suggest necrotizing enterocolitis rather than the correct diagnosis.

THERAPEUTIC CONSIDERATIONS

Barium enema or air enema may be used to diagnose and to treat ileocolic intussusception. The hydrostatic or pneumatic pressure of the enema is used to drive the infolded segment of bowel in a retrograde direction to its normal position. Surgery is required to reduce intussusceptions that do not respond to this pressure and to treat children whose clinical status precludes radiologic intervention. Children with fever, elevated white blood cell count, peritoneal signs, or marked systemic toxicity should have immediate surgery because these findings suggest perforated bowel or gangrenous gut. Spontaneous reduction may occur, often as a result of general anesthesia, and about 14% of children with documented intussusception may have none of these findings at surgery.^{83,84}

When there is evidence of small bowel obstruction or the presence of symptoms for more than 24 hours, the success rate for reduction is decreased.⁸⁷⁻⁸⁹ Whereas the success rate may be greater than 75% in children seen acutely, it is half of that rate in those who have symptoms for more than 48 hours. Because the only alternative to hydrostatic or pneumatic reduction is surgery, with its increased morbidity and cost, reduction should be attempted in all children who do not have the medical problems described previously.

Recurrent intussusception develops in 7% to 10% of the children who have had successful reductions. Second and even third episodes of intussusception do not necessarily indicate that there is a lead point. In a large series, only 10% to 20% of children with recurrence had lead points found at surgery.⁹⁰ For this reason, hydrostatic or air reduction should be attempted despite recurrence.

Children with Henoch-Schönlein purpura, recent abdominal surgery, or cystic fibrosis have an increased incidence of intussusception. Standard reduction methods may work in these populations, but they are usually less successful in children with Henoch-Schönlein purpura.⁹¹

RADIOLOGIC FINDINGS

The diagnosis of intussusception is often suggested on conventional radiographs when the amount of intestinal gas is subnormal; bowel loops are displaced from the right hypochondrium;

the appendix, if air filled, is in an abnormal location; or the intussusceptum can be identified as a soft tissue mass.⁹²⁻⁹⁴ When there is a suspicion of intussusception, the child may go directly to a contrast enema with barium, air, or water-soluble agents performed for diagnosis and treatment.

In many institutions, a diagnostic sonogram is performed. Sensitivity for diagnosis approaches 100% and specificity is more than 90%.⁹⁵⁻⁹⁷ Pitfalls of sonographic diagnosis include false-positive results produced when the bowel is thickened for other reasons, such as lymphoma or Crohn's disease, and false-negative results when the amount of bowel gas present precludes a complete abdominal examination. Detection of false lead points has also been reported.⁹⁴

The therapeutic enema examination is performed only in the medically stable child. Surgical consultation should be obtained before the study in case reduction is unsuccessful or a complication occurs. The lethargic or dehydrated child should be resuscitated before the examination is started. A large-bore catheter (with or without inflatable balloon) is placed securely in the rectum, and the buttocks are firmly taped shut. First the barium enema and then the air enema are described.

The bag of barium or water-soluble contrast agent is suspended 36 to 39 inches above the fluoroscopy table. Flow of contrast material is continued until the colon is filled and there is free reflux into the small bowel or until the intussusceptum is encountered (Fig. 118-14). The contrast medium bag remains open to the patient throughout the study to maintain a constant pressure in an attempt to push the gut to its original position.

Figure 118-14 Intussusception. A persistent filling defect is seen on barium enema examination in the ileum in this child who had a normal-appearing colon. Because the sonogram that preceded this study showed the intussusception, it was necessary to reflux into more ileal loops than usual to confirm and treat the problem.

Manual pressure on the abdomen should be avoided because it may increase the risk of perforation. The flow of contrast material continues as long as there is retrograde motion of the intussusceptum. When there is a standstill, the bag should remain open to the patient for another 3 to 5 minutes. If there is no movement during this period, the contrast material is drained from the colon, and the child is allowed to rest for a few minutes. Enema reduction is attempted again, and this sequence is followed up to three times. If incomplete or no reduction has occurred, surgery is indicated. Successful reduction with this technique occurs in almost 90% of children. Recent literature suggests that in some children, delayed repeated attempts at intussusception reduction are successful and may avert surgery.^{90,98,99} Analgesia and sedation may be given if the first reduction attempt is unsuccessful.¹⁰⁰ This tends to make the child more comfortable and may aid in spontaneous reduction. Children with suspected intussusception are not routinely sedated before beginning of a contrast enema because the medication may obscure the nature of the abdominal process in children who do not have an intussusception. Glucagon, an effective smooth muscle relaxant, has not proved helpful in intussusception reduction in children.¹⁰¹

Barium dissecting between the intussusceptum and the intussusciptens has been reported as a sign of nonreduction and is associated with an increased incidence of necrotic bowel (Fig. 118-15). However, reduction is possible in as many as 40% of these children, and a nonvigorous attempt, perhaps with water-soluble contrast medium, may avoid surgery.

Reduction exists only when there is free reflux of contrast material into small bowel loops. They should be carefully

Figure 118-15 Dissection sign of intussusception on barium enema study. Contrast medium is seen along the sides of the intussusception, which has a coil-spring appearance. When this sign is observed, the likelihood of successful reduction is diminished, although reduction is still possible.

Figure 118-16 Sonography of intussusception. **A.** The target (arrows) appearance of intussusception is demonstrated on this longitudinal sonogram. The hypoechoic structures anteriorly are dilated bowel loops. **B.** Transverse scan of a different patient shows the parallel echogenic mucosa (arrows) of the intussusciens and intussusceptum.

evaluated by fluoroscopy and on filled and postevacuation radiographs in an attempt to find a lead point.

After reduction, the ileocecal valve may be edematous and may simulate a persistent intussusception or lead point.¹⁰² In older children, a delayed abdominal radiograph is helpful in identifying a residual cecal mass that may represent lymphoma or another lead point.

Perforation can occur during the reduction procedure at the site of the intussusception, the distal colon, or the rectum if the balloon is overinflated.^{103,104} Perforation is rare, occurring in less than 1% of reductions.

Water-soluble contrast medium or air should be used when there is concern about the viability of the underlying bowel, if symptoms have been present for more than 48 hours, and in neonates and infants. Water-soluble contrast medium exerts less hydrostatic pressure than barium, allowing the enema bag to be raised slightly higher than the standard 3 feet.¹⁰⁵

Intussusception reduction by enema with room air is widely used.¹⁰⁶⁻¹¹⁰ This technique has an impressive success rate, few complications, and many advantages. No foreign agent is introduced if there is perforation into the peritoneal cavity, and reduction attempts are less messy. Original reports indicated that radiation exposure was reduced because fluoroscopy time was often shorter and lower fluoroscopic techniques can be used, but a later article confirmed that fluoroscopy times were widely varied and depended on the radiologist and the ease of reduction.¹⁰⁷ For the novice, it may be difficult to determine when reduction has occurred because air may pass into and distend the small bowel before complete reduction has occurred.^{109,110}

Air reduction has many of the same requirements as hydrostatic reduction: placement of a rectal tube, a good seal of the rectum, and fluoroscopy. Air can be delivered by intermittent manual insufflation or through a continuous delivery system. Pressure is controlled by manometry so that the desired pressures are reached but not exceeded. Low pressure (60 mm Hg) and a low flow rate (1 L/min) may aid visualization of the intussusceptum at the beginning of the study, but pressures between 80 and 120 mm Hg are used routinely during most of the study.¹⁰⁶ Tension pneumoperitoneum secondary to perforation during air reduction may be life-threatening.¹⁰⁴ An 18-gauge

needle is standard equipment to immediately perform a paracentesis.

The sonographic findings of intussusception are well described.^{94-97,110-114} The mass of infolded bowel and the layering of the bowel walls produce a target or doughnut appearance on transverse scans (Fig. 118-16A) and a pseudokidney or sand-wich sign on longitudinal scans (Fig. 118-16B). Sonography may be diagnostic and therapeutic. At some institutions, Ringer, Hartmann, or saline solution enemas or air enemas are used to reduce the intussusception under sonographic guidance.¹¹⁵⁻¹¹⁸ The CT appearance of intussusception has been described in adults (see Chapter 62) and children.¹¹⁹ CT is not a useful screening technique because of radiation dose considerations and expense. CT or sonography may be of use in the child with no visible intussusceptum on enema but a competent ileocecal valve. In this setting, it is important to differentiate the child with a reduced intussusception from the child with residual ileoileal or other intussusception variant.

Volvulus of the Colon

CLINICAL FINDINGS

Volvulus of the colon is rare in children and occurs most commonly in the setting of malrotation and other anomalies of mesenteric attachment; constipation associated with mental retardation, HD, or cystic fibrosis; or aerophagia.¹²⁰⁻¹²³ Cecal volvulus may include twisting of the adjacent small bowel; it has been reported in children who have achieved continence by cecostomy button or tube and antegrade enema.¹²⁴

The very young are spared, and the presentation of childhood volvulus is usually between 7 and 10 years. Colonic volvulus generally and sigmoid volvulus specifically occur four to five times more frequently in boys than in girls. At presentation, the child has abdominal pain and, less frequently, vomiting accompanying the physical findings of abdominal distention and tenderness. This presentation may simulate intussusception, although this diagnosis would be unlikely in an older child.

Treatment consists of a diagnostic enema and proctoscopy or colonoscopy with or without insertion of a large-bore

Figure 118-17 Sigmoid volvulus. Twisting of the colon produces narrowing just above the rectum. The segment above the volvulus is dilated and full of feces.

catheter for decompression. Operative treatment is needed if decompression is not achieved or if the volvulus recurs, which it does in one third of cases. If there are signs of peritonitis, surgery is indicated because gangrenous bowel can result from vascular compromise of the involved gut.

RADIOLOGIC FINDINGS

In patients with volvulus, conventional radiographs may be interpreted as normal, show nonspecific changes of colonic or small bowel obstruction, or less commonly demonstrate the bean-shaped, abnormally twisted loop. The value of the northern exposure sign (i.e., the dilated, volvulated sigmoid colon projects above the transverse colon) has not been determined in children.¹²⁵ Cecal volvulus may be manifested as an air-filled structure in the left midabdomen or left upper quadrant. Conventional radiographs are most useful for excluding other causes of abdominal pain and free air.

The contrast enema study characteristically demonstrates the narrowing, twisting, or bird-beak deformity of the volvulus (Fig. 118-17). The pressure of the enema may untwist the affected segment. Further discussion of volvulus can be found in Chapter 62.

Juvenile Polyps

CLINICAL FINDINGS

Juvenile polyps are benign, “inflammatory” polyps that are not hereditary or associated with inflammatory bowel disease. They are slightly more common in males than in females.¹²⁶⁻¹²⁹ These

Figure 118-18 Juvenile polyps. Double-contrast barium enema examination demonstrates three polyps, two on stalks in the region of the splenic flexure (arrows) and the third en face (arrowheads) in the transverse colon.

polyps are rare in the neonate and are manifested in the middle and latter part of the first decade of life with blood in the stools. The bleeding is not accompanied by diarrhea or extragastrointestinal symptoms to suggest infectious or inflammatory bowel disease. Inspection of the anus can exclude fissure or tear as a cause of blood. On occasion, the polyp may be manifested as a prolapsing rectal mass. These polyps should be differentiated from those seen in juvenile polyposis, an autosomal dominant form of polyposis with few distinguishing extracolonic manifestations, and from polyps that occur in syndromes such as Peutz-Jeghers syndrome and familial adenomatous polyposis.¹²⁹⁻¹³² Because up to one third of these polyps are proximal to the splenic flexure, colonoscopy is recommended. Treatment consists of polypectomy at the time of colonoscopy.

RADIOLOGIC FINDINGS

Juvenile polyps are best demonstrated on double-contrast barium enema studies. Although most juvenile polyps are left sided, the entire colon must be carefully assessed. Demonstration of one polyp should not detract from the search for an additional one because approximately 20% to 30% of children have more than one juvenile polyp. Most polyps appear smooth and pedunculated (Fig. 118-18). The radiologic criteria for differentiating benign from malignant polyps in adults are of little value in children because virtually all juvenile polyps are benign, regardless of their appearance.

Imaging of polyps by sonography with compression of the colon and CT colonography are emerging areas of interest.¹³³⁻¹³⁵ However, colonoscopy is the first line of evaluation in most settings.

Colon Carcinoma

Primary colon cancer is rare in children, and on pathologic examination, these cancers are more often mucinous or colloid variants.¹³⁶⁻¹⁴² Most occur in the rectum and sigmoid colon. These cancers may arise spontaneously or may result from ulcerative colitis or familial adenomatous polyposis.

CLINICAL FINDINGS

A mass is palpable in about 10% of patients. The symptoms of colon cancer (e.g., vomiting, pain, constipation, bleeding) warrant early and complete evaluation, although the rarity of this neoplasm in children tends to delay a thorough diagnostic work-up. Consequently, the disease is often advanced at the time of diagnosis. Patients do poorly despite surgery and chemotherapy.

The differential diagnosis of colon cancer is limited. Non-neoplastic lesions such as intussusception, appendicitis, gastroenteritis, and parasitic infestations should be considered and excluded with appropriate tests. Obstruction, mass, and rectal bleeding can also be the presenting signs of a number of other neoplasms, including hemangioma, lymphoma, leiomyomas, and other spindle cell tumors.¹⁴¹

RADIOLOGIC FINDINGS

Single- and double-contrast barium enema characteristics of colon cancer in children are identical to those found

in adults (see Chapter 59). Mucosal irregularity or narrowing of the caliber of the colon with a typical apple-core deformity may be present. As in adults, sonography or CT is useful in looking for local, metastatic, or recurrent disease.

Fibrosing Colonopathy

CLINICAL FINDINGS

Fibrosing colonopathy (FC) has been recognized in children and adults with cystic fibrosis.¹⁴³⁻¹⁴⁸ It is a complication of enzyme replacement therapy, and it is usually seen in children in the first decade of life. It is unclear whether FC is related to high-dose preparations or to the total dose of enzyme that has been received. FC results in luminal narrowing of the colon and is distinct from Crohn's disease. Although patients with FC have diarrhea and abdominal pain, FC may not be immediately diagnosed because enzyme-refractory diarrhea and abdominal pain are fairly common in children with cystic fibrosis. In patients with FC and obstruction, distal intestinal obstruction syndrome or intussusception may be simulated. A contrast enema can differentiate these complications.

Treatment consists of decreasing the enzyme dose and amount of fat in the diet. Severe obstruction is common and may require surgery.¹⁴⁹

RADIOLOGIC FINDINGS

Barium enema examination reveals colonic stricture of varying severity extending distally from the cecum.¹⁴⁵ The rectum is usually spared. The colon is foreshortened, and the haustra are obliterated in the affected segments.^{150,151}

Diseases of the Pediatric Gallbladder and Biliary Tract

JENNIFER L. NICHOLAS

CHAPTER OUTLINE

Imaging Modalities

Normal Gallbladder

Normal Bile Ducts

Evaluation of Infants and Children with Cholestasis

Neonatal Jaundice

Biliary Atresia

Alagille's Syndrome

Progressive Familial Intrahepatic Cholestasis

Choledochal Malformations

Caroli's Disease

Bile Plug Syndrome or Inspissated Bile Syndrome

Gallbladder Disease

Cholelithiasis

Acalculous Cholecystitis

Gallbladder Dyskinesia

Gallbladder Hydrops

Bile Duct Disease

Choledocholithiasis

Biliary Changes with Cystic Fibrosis

Primary Sclerosing Cholangitis

Neoplasms

Imaging Modalities

Ultrasound is typically the first imaging modality used in the evaluation of children with suspected biliary disease because it is noninvasive and relatively inexpensive and does not involve contrast agents, sedation, or radiation exposure. Ultrasound is particularly useful in differentiating obstructive from nonobstructive causes of jaundice.¹ In general, the only preparation needed for an ultrasound study in the work-up of suspected biliary disease is for the child to have nothing by mouth for as close to 4 to 6 hours as possible to ensure optimal distention of the biliary system.

Computed tomography (CT) and magnetic resonance imaging (MRI) can also be useful in the evaluation of the biliary system in children, but CT exposes the child to radiation and both imaging modalities may require sedation. Specific protocols for evaluating the biliary system have been developed for CT and MRI. CT cholangiography, performed after the intravenous administration of a contrast agent that is excreted by the liver into the biliary system (meglumine iodoxamic acid), is not typically used in the pediatric population.² Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive

means of evaluating the biliary system, the surrounding liver parenchyma, and other abdominal viscera that can usually be performed without administration of a contrast agent and does not expose the child to radiation.² MRCP is limited in neonates and infants, however, as biliary ducts less than 1 mm in diameter are difficult to visualize on MRCP.³ In preparation for MRCP, it is essential that the child be given nothing by mouth for as close to 4 to 6 hours as possible so that the biliary system is optimally distended and the stomach is empty.³ During acquisition of the images for MRCP, breath-hold techniques can be used in children who are able to cooperate, and non-breath-hold techniques with respiratory gating can be used in children who are not able to cooperate.^{3,4}

Percutaneous transhepatic cholangiography, percutaneous cholecystocholangiography, intraoperative cholangiography, and endoscopic retrograde cholangiopancreatography (ERCP) are also used in evaluation of the pediatric biliary system, but they are invasive examinations, expose the child to radiation and sedation, and can be technically challenging. ERCP, for example, has a complication rate in pediatric patients of one in three (33%), which is higher than the complication rate for adults.⁵

Nuclear medicine hepatobiliary scintigraphy, which is performed with either ^{99m}Tc-disofenin ([2,6-diisopropylacetanilido]-iminodiacetic acid) or ^{99m}Tc-mebrofenin (bromo-2,4,6-trimethylacetanilidoiminodiacetic acid), provides more physiologic information than anatomic information, particularly regarding the patency of the biliary system.

Normal Gallbladder

Ultrasound is an ideal imaging modality for evaluating the gallbladder in children because it allows real-time evaluation of the gallbladder in multiple planes and with the patient in various positions. The normal pediatric gallbladder is approximately 1.3 cm in length in neonates and 3.4 cm in length in infants and less than 1 cm in width.⁶ The average length of the gallbladder in a 16-year-old is 8 cm, with an average width of less than 3.5 cm.⁷

The normal sonographic appearance of the gallbladder wall is well defined, hyperechoic, and less than 3 mm in thickness when the child is fasting.^{6,7} Duplication of the gallbladder is rare⁸ and is often asymptomatic, but when it is encountered, it may be mistaken for a pathologic process such as choledochal malformation, dilated bile ducts, or gallbladder diverticulum (Fig. 119-1). Other congenital anomalies of the gallbladder include ectopia (most commonly retrohepatic, intrahepatic, or suprahepatic), septations, and agenesis.⁶ The normal pediatric gallbladder may have folds or kinks, which can mimic pathologic processes such as stones and dilated bile ducts. Imaging in more than one plane or with the patient in different positions

Figure 119-1 Duplication of the gallbladder. **A** and **B.** Sonograms in two planes demonstrate two gallbladders (arrows and arrowheads) in a 10-year-old child with biliary colic.

Figure 119-2 Normal gallbladder with a fold. **A.** Male infant at 21 days old. The sonographic image demonstrates a fold (arrow) that mimics a septum traversing the gallbladder lumen. **B.** Imaging in another plane demonstrates that the gallbladder lumen is not compartmentalized. The fold simulates focal thickening of the gallbladder wall (arrow).

can help differentiate normal folds from abnormal pathologic processes (Fig. 119-2).⁶

Gallbladder wall thickening in children, which is defined as more than 3 mm in thickness, can be seen in the setting of acute or chronic cholecystitis,⁶ hypoalbuminemia, ascites, systemic venous hypertension,⁹ and acute hepatitis.¹⁰ Children with ascites and hypoalbuminemia can have normal gallbladder wall thickness, however.⁹ Cholecystitis can occur in children without gallbladder wall thickening as well.⁹ The gallbladder wall may appear falsely thickened if fluid is trapped in the mesentery between the gallbladder and liver, creating a halo effect, or if fluid is otherwise surrounding the intraperitoneal gallbladder.⁹ Technical factors, such as the angle of the transducer, can also affect the appearance of the gallbladder wall. If the gallbladder is not optimally distended because of a contraction from a recent meal, the gallbladder wall may appear falsely thickened, and repeated imaging after the patient has been fasting for 4 to 6 hours is recommended for more accurate evaluation.

Normal Bile Ducts

Bile excreted by hepatocytes of the liver is collected by bile canaliculi that merge into the canals of Hering. Bile then flows into interlobular bile ducts, more peripheral intrahepatic bile ducts, and then into the left and right hepatic ducts. The left and right hepatic ducts merge into the common hepatic duct, which exits the liver and joins the cystic duct (from the gallbladder), which then forms the common bile duct. The common bile duct then joins the pancreatic duct, forming the ampulla of Vater, which delivers the bile to the second portion of the duodenum.

Peripheral intrahepatic ducts are not typically visualized on ultrasound, CT, or MRI (even MRCP) unless they are dilated. The normal left and right hepatic ducts may be seen on ultrasound, MRI, and CT in older children. The common hepatic duct, cystic duct, and common bile duct may be visualized more readily, but their small size can make visualization challenging. As measured on ultrasound from inner wall to inner wall, the

Figure 119-3 Normal findings on MRCP. MRCP was obtained to evaluate the biliary tract in a child with sickle cell disease. **A.** The coronal, thick-slab, T2-weighted image demonstrates patency of the common bile duct (arrow), the common hepatic duct, and the right and left hepatic ducts (arrowheads). There is loss of signal where the hepatic artery crosses at the confluence of the right and left hepatic ducts. Individual source images (not shown) demonstrate duct patency. The gallbladder is distended with bile (asterisk). **B.** Coronal half-Fourier acquisition single-shot turbo spin-echo (HASTE) image demonstrates the flow void in the main hepatic artery (white arrow) and right branch of the hepatic artery (arrowhead). The black arrow marks the origin of the common hepatic duct.

diameter of the common bile duct should be less than 1.6 mm in children younger than 1 year and less than 3.3 mm during childhood and early adolescence.¹¹ The cystic duct is usually seen only if it is dilated, and even then, only the distal portion of the cystic duct is typically visualized.⁶

On MRCP, the pediatric biliary tree is considered normal if the right hepatic, left hepatic, common hepatic, and common bile ducts are visualized, are of normal caliber, and have confluent, uniform branching (Fig. 119-3).¹²⁻¹⁴ In neonates, however, the extrahepatic biliary ducts may be the only ducts visible.

Evaluation of Infants and Children with Cholestasis

NEONATAL JAUNDICE

Normal transient physiologic jaundice (unconjugated hyperbilirubinemia) can occur in term and preterm infants in the first 2 weeks of life.¹⁵ The Cholestasis Guideline Committee recommends evaluation for cholestasis (abnormal accumulation of conjugated bilirubin), however, in jaundiced, non-breast-fed infants who are more than 2 weeks old.¹⁵ Breast-fed infants may have elevated bilirubin during the first 3 weeks of life, but hyperbilirubinemia in these babies should be considered abnormal if the urine is dark or the stools are light.¹⁵ Cholestasis is diagnosed when the serum conjugated bilirubin concentration is more than 1.0 mg/dL if the total serum bilirubin concentration is less than 5.0 mg/dL or when it is more than 20% of the total serum bilirubin concentration if the total serum bilirubin concentration is less than 5.0 mg/dL.

Transient neonatal jaundice can be due to hemolysis, hepatic infection, sepsis, metabolic diseases, bile plug syndrome, or adrenal hemorrhage. Some medications and total parenteral nutrition can also cause transient jaundice. Neonatal hepatitis, biliary atresia, and choledochal malformation are the most common causes of persistent neonatal jaundice,¹ with hepatitis

and biliary atresia accounting for 70% to 80% of cases.¹⁶ Alagille's syndrome and spontaneous bile duct perforation are less common causes of persistent neonatal jaundice.¹⁶ Caroli's disease is a congenital abnormality of the intrahepatic bile ducts that can also cause persistent jaundice, but clinical presentation more commonly occurs in childhood or adolescence.¹⁷

Biliary atresia is the most common cause of persistent neonatal jaundice that requires surgical intervention. Other less common surgically amenable causes of persistent neonatal jaundice include inspissated bile syndrome, choledochal malformation, and spontaneous perforation of the bile ducts.¹⁸ The initial imaging study in a child with neonatal jaundice is usually an ultrasound examination of the abdomen and pelvis. The liver size, vasculature, parenchymal echogenicity and echotexture, and intrahepatic and extrahepatic biliary ducts are evaluated with gray-scale and Doppler imaging. If a gallbladder is present, it is evaluated for size, wall thickness, presence of stones or sludge, and pericholecystic fluid. The spleen and pancreas are also evaluated. Ultrasound of the abdomen and pelvis provides good anatomic evaluation for potential sources of cholestasis; hepatocyte function and biliary drainage can be evaluated with nuclear medicine hepatobiliary scintigraphy, preferably performed with ^{99m}Tc-mebrofenin.

BILIARY ATRESIA

Background

Biliary atresia is a progressive, fibrosing, obliterative disease that affects the biliary tree. Biliary atresia typically begins in the neonatal period but may begin before birth.^{19,20} Biliary atresia results in cholestasis, which then leads to hepatic fibrosis and cirrhosis.²⁰ Children with biliary atresia typically present with persistent neonatal jaundice and often also have icterus or clay-colored (acholic) stool.²¹ Biliary atresia occurs in 1 of 8000 to 16,700 live births, with a higher incidence in Asian populations.²²⁻²⁴

Figure 119-4 Schematic of Ohi used in the classification of biliary atresia. **A.** The three main types of biliary atresia (type I is considered surgically “correctable”). **B.** The subtypes for biliary atresia of the distal biliary ducts. **C.** The subtypes for biliary atresia of the proximal biliary ducts. (From Superina R, Magee JC, Brandt ML, et al: *The anatomic pattern of biliary atresia identified at time of Kasai hepatopuertoenterostomy and early postoperative clearance of jaundice are significant predictors of transplant-free survival.* *Ann Surg* 254:577–585, 2011.)

Several classification systems for biliary atresia have been developed, generally based on which part of the biliary tree is involved and to what degree.¹ The classification system for biliary atresia initially proposed and Ohi^{25,26} is one of the more widely used. In the system developed by Ohi, type I is atresia of the common bile duct, with patency of the proximal biliary ducts (right hepatic, left hepatic, and common hepatic), and it is considered to be the surgically “correctable” type of biliary atresia. Type II is atresia of the hepatic duct. Type III is involvement of the extrahepatic biliary tree and intrahepatic ducts of the porta hepatis.²⁵ Varying degrees of atresia may occur in the distal ducts, ranging from hypoplasia to fibrosis, aplasia, or a miscellaneous combination of these degrees of atresia (subtypes a to d, respectively). Involvement of the proximal ducts is further divided into subtypes that are assigned lowercase Greek letters: alpha (α) is dilation of the proximal ducts, beta (β) is hypoplasia of the proximal ducts, gamma (γ) involves a bile lake at the porta hepatis, mu (μ) is fibrosis of the proximal ducts, nu (ν) is a fibrous mass at the porta hepatis, and omicron (\omicron) is aplasia of the proximal ducts (Figs. 119-4 and 119-5).

Associated Anomalies and Malformations

Approximately 70% to 85% of infants with biliary atresia will not have any other anomalies or malformations, which has been referred to as perinatal biliary atresia.^{27–29} Typically, these children are born without jaundice, but jaundice develops and

stools become progressively acholic within the first 2 months of life.

Approximately 10% to 15% of infants with biliary atresia have associated laterality malformations, which is known as biliary atresia splenic malformation³⁰ or embryonal biliary atresia. Abnormalities associated with biliary atresia include situs inversus, symmetric bilobed liver, asplenia or polysplenia, intestinal malrotation, interrupted or absent inferior vena cava, preduodenal portal vein, aberrant hepatic artery, and cardiac anomalies.^{30,31} If polysplenia or situs inversus is encountered in a jaundiced infant, biliary atresia is almost invariably present.¹⁸ The association is important because the complex anatomy in patients with laterality malformations complicates the surgical treatment of biliary atresia.²³

The remaining 5% to 10% of biliary atresia cases are associated with other congenital malformations, including intestinal atresia, imperforate anus, kidney anomalies, and cardiac anomalies.^{28,32,33}

Treatment

If it is untreated, biliary atresia is fatal, with an average survival of 18 months.³⁴ In patients with biliary atresia, the goal is to achieve adequate biliary drainage with the Kasai procedure (also known as the Kasai portoenterostomy, hepatic portoenterostomy, and hepatopuertoenterostomy). The Kasai procedure involves excision of the obliterated biliary remnant with

Figure 119-5 Biliary atresia: cholangiographic features. **A.** Intraoperative cholangiography is performed by catheterization of the gallbladder (asterisk) and injection of contrast material. This infant has an extremely hypoplastic but patent common bile duct (arrow). There is no filling of the common hepatic duct or intrahepatic ducts. The pancreatic duct (arrowhead) is opacified. **B.** Normal findings on intraoperative cholangiography in an infant. The gallbladder (asterisk) is cannulated. The union of the cystic duct and common hepatic duct forms the common bile duct (arrow). The right and left hepatic ducts are opacified (arrowheads), and intrahepatic duct branching is evident.

anastomosis of the portal plate to the small bowel with a Roux-en-Y hepatojejunostomy. For the biliary atresia to be considered surgically correctable, a portion of the proximal common hepatic duct must be patent, which can be directly anastomosed to the jejunum after the resection of the fibrotic bile duct remnant, ideally preventing the long-term sequelae of biliary atresia and the need for liver transplantation. Unfortunately, the truly correctable type of biliary atresia is uncommon, accounting for only approximately 10% to 15% of cases. Even though the remaining forms of biliary atresia are not considered correctable surgically, the Kasai procedure is used palliatively until a liver transplant is needed, with a survival rate of more than 95%.¹⁸ Adequate biliary drainage after a Kasai procedure has been defined as a total bilirubin concentration of less than 2.0 mg/dL anytime within the first 3 months after surgery.²⁶

It was initially accepted that the Kasai procedure should be performed before an infant diagnosed with biliary atresia reaches 2 months of age.³⁵ Subsequently, however, this was not the conclusion of a more comprehensive analysis from the Japanese registry,³⁶ nor was it the conclusion of Davenport, who reported a 5-year 45% transplant-free survival in a smaller cohort of children who underwent the Kasai procedure at more than 100 days of age.³⁷ A collaborative North American study, which prospectively evaluated 530 patients with biliary atresia from 2004 to 2010, found that infants younger than 75 days undergoing the Kasai procedure were no more likely than infants older than 75 days to achieve adequate biliary drainage (total bilirubin concentration of less than 2.0 mg/dL within the first 3 months).²⁶ In the same study, however, Suprina and colleagues²⁶ did show that having the Kasai procedure done before 75 days of age was associated with improved transplant-free survival, suggesting that efforts to identify and to treat infants with biliary atresia as early as possible are worthwhile.

Cholangitis is a serious potential complication of the Kasai procedure that can lead to sudden cessation of bile drainage. The greatest risk factor for development of cholangitis after a Kasai procedure is inadequate biliary drainage. Cholangitis

should be suspected when the child has fever and acholic stools or fever and jaundice with an elevated direct bilirubin level and positive C-reactive protein result.^{38,39} Some investigators expand the diagnosis of cholangitis to include any unexplained fever in a patient who has had a Kasai procedure. Most patients who have undergone the Kasai procedure have at least one episode of cholangitis, and 90% occur in children younger than 2 years.³⁹ Episodes of cholangitis in this population have been shown to adversely affect survival rates.³⁹

Imaging

Ultrasound, nuclear medicine hepatobiliary scintigraphy, CT, and MRI are the primary imaging modalities used in the work-up for biliary atresia. When necessary, transhepatic cholangiography, intraoperative cholangiography, and traditional angiography may be used. Preoperative definition of the patient's anatomy with Doppler ultrasound, CT, MRI, and angiography is used in technical planning of the surgical procedure. Traditional angiography may be necessary to demonstrate the location and size of the portal trunk in cases in which it is not seen by CT or MRI.⁴⁰

Ultrasound should be the initial imaging modality for infants with cholestatic jaundice and suspected biliary atresia.²² The infant is kept fasted for as close to 4 hours as possible before the ultrasound examination in an attempt to maximize distention of the biliary tree and gallbladder, if one is present. A high-frequency linear transducer or microconvex transducer is used for optimal visualization of the biliary system.^{20,22}

Sonographic findings in children with biliary atresia are variable. The liver parenchyma may be normal in echogenicity and echotexture,⁴ or there may be absence of identifiable bile ducts resulting in a homogeneous appearance of the liver parenchyma (Fig. 119-6).¹⁸ If the patient presents later in the course of the disease, findings of cirrhosis and portal hypertension may be present (Fig. 119-7). The common bile duct may not be seen. If the liver is not interrogated by color Doppler imaging, the hepatic artery can be mistaken for the common bile duct, resulting in a false-negative study. False-negative examination results can also occur when there is a patent portion of the

Figure 119-6 Biliary atresia: sonographic features. **A.** Longitudinal sonogram of a 22-day-old girl with cholestatic jaundice. The liver has a normal, uniform echotexture. The intrahepatic inferior vena cava (arrowhead), hepatic veins, and portal veins (arrow) are seen, but bile ducts are not identified. **B.** A small gallbladder (arrow) with an irregular wall is identified. There is no bile duct dilation. Biliary atresia was confirmed with nuclear scintigraphy, liver biopsy, and intraoperative cholangiography before treatment with a Kasai procedure.

Figure 119-7 Biliary atresia: progression to cirrhosis with portal hypertension and ascites. Gray-scale and color Doppler images of the liver with a high-frequency linear transducer in a 3-month-old boy with biliary atresia show nodular contour of the liver surface (arrow), ascites (asterisk), and an enlarged hepatic artery (arrowhead). This patient was not a candidate for the Kasai procedure because he presented after he had ascites and cirrhosis. He received a liver transplant approximately 1 month later.

common bile duct²¹ or if there is cystic dilation of the extrahepatic duct.¹⁸

When the hepatic artery is correctly identified, its size may be helpful in making the diagnosis of biliary atresia. It has been shown that the diameter of the right hepatic artery in patients with biliary atresia (1.9 ± 0.4 mm) is significantly larger than the diameter of the hepatic artery in infants with hepatitis (1.4 ± 0.3 mm) and infants in the control group (1.2 ± 0.2 mm).⁴¹ In the same study, the hepatic artery diameter-to-portal vein diameter ratio in the biliary atresia group (0.52 ± 0.12) was larger than that in hepatitis (0.40 ± 0.07) and control (0.40 ± 0.10) groups ($P < .001$).⁴¹ On the basis of these findings, cutoff values for diagnosis of biliary atresia were 1.5 mm (sensitivity, 92%; specificity, 87%; accuracy, 89%) for hepatic artery diameter and 0.45 for hepatic artery diameter-to-portal vein diameter ratio (sensitivity, 76%; specificity, 79%; accuracy, 78%).⁴¹

Another ultrasound finding that can be helpful in the diagnosis of biliary atresia is a focal triangular or tubular hyperechoic structure just anterior and slightly superior to the main portal vein bifurcation (Fig. 119-8), known as the triangular cord sign. This echogenic structure represents the fibrotic remnant of the obliterated common bile duct.^{4,20,22,42,43} Flow is not seen within the triangular cord on Doppler evaluation. The triangular cord may not be obvious in the early stages of the disease, or it may be obscured by a large right hepatic artery.⁴² The triangular cord can also be masked by diffuse periportal hyperechogenicity due to inflammation or cirrhosis, or it may be difficult to appreciate if the fibrotic cord is small.²⁰ Short-term follow-up ultrasound is warranted if the infant has findings on initial ultrasound that appear normal or that suggest neonatal hepatitis but the cholestatic jaundice is not improving or is worsening.⁴⁴

Figure 119-8 Biliary atresia: triangular cord sign on ultrasound. The triangular cord sign describes the fibrotic, obliterated common bile duct in infants with biliary atresia. It is seen as a focal hyperechoic area just cephalad to the main portal vein bifurcation, or it can be measured as the echogenic anterior wall of the right portal vein (arrows). The hypoechoic area within this is a branch of the right hepatic artery. (Courtesy Myung-Joon Kim, MD, Yonsei University College of Medicine, Severance Hospital, Seoul, Korea.)

A triangular cord larger than 4 mm in a neonate with cholestatic jaundice has been shown to be 80% sensitive and 98% specific and to have positive and negative predictive values of 94% for the diagnosis of biliary atresia.⁴⁵ Round, linear, or tubular hypoechoic or cystic lesions within the triangular cord have been described that are cleftlike cystic lesions within the fibrotic mass histopathologically.⁴ These cystic clefts can also be seen as triangular areas of increased signal intensity on T2-weighted MRCP images.⁴

The gallbladder is usually small or absent in patients with biliary atresia,^{4,14,20-22} but visualization of a normal gallbladder does not exclude the diagnosis of biliary atresia.⁴² Jaundiced, preterm infants receiving total parenteral nutrition without biliary atresia can also have small gallbladders.²⁰ The gallbladder ghost triad has been described in association with biliary atresia: an atretic gallbladder (<1.9 cm long); thinned mucosa or lack of a smooth, complete echogenic gallbladder mucosal lining with indistinct walls; and a knobby, irregular or lobular gallbladder contour (Fig. 119-9).²⁰ These findings are presumed to be caused by the atretic state, immaturity, and lack of function of the gallbladder in infants with biliary atresia. Gallbladder wall thickening is not a feature of biliary atresia, but it has been described in 25% of jaundiced infants without biliary atresia and may be useful in directing the work-up away from the diagnosis of biliary atresia.²⁰

When ultrasound is not diagnostic of biliary atresia, the next diagnostic test is usually a nuclear medicine hepatobiliary scintigraphy study.⁴² This study is performed with ^{99m}Tc and an iminodiacetic acid derivative, preferably mebrofenin,⁴⁶ because of its higher hepatic excretion.⁴⁷ Ideally, a 3- to 7-day course of oral phenobarbital (5 mg/kg/day in two divided doses)^{46,47} is given to the child in preparation for the examination because it is thought that phenobarbital enhances bile excretion and flow,

Figure 119-9 Biliary atresia: gallbladder ghost triad on ultrasound. The combination of an atretic gallbladder with irregular mucosa and wall contour (arrow) has been called the gallbladder ghost triad. It is associated with biliary atresia. (Courtesy Myung-Joon Kim, MD, Yonsei University College of Medicine, Severance Hospital, Seoul, Korea.)

which can help differentiate biliary atresia from neonatal hepatitis. If the infant is approaching the age before which a Kasai procedure is ideally performed (60-75 days), the hepatobiliary study may be attempted without the phenobarbital preparation or with a shorter 2- to 3-day pretreatment with ursodeoxycholic acid (20 mg/kg/day in two divided doses, continued until the test is finished)^{47,48} in an effort to save time and to prevent a delay in the diagnosis.

According to the practice guidelines of the Society of Nuclear Medicine, an infant who is having a hepatobiliary scan should be kept fasted for at least 2 hours before the intravenous administration of 1 mCi of ^{99m}Tc-mebrofenin.⁴⁷ Anterior images are then acquired dynamically, starting at the time of injection and continuing for 60 minutes, at 1 minute per frame.⁴⁷ Delayed images in the anterior and right lateral projections are obtained after a diaper change, including 5-minute images at 4 to 6 hours and 10-minute images at 24 hours if no radiopharmaceutical has been visualized in the small bowel.

The findings on the hepatobiliary scintigraphy study are considered normal if the hepatic parenchyma is visualized almost immediately after intravenous administration of the isotope, followed sequentially by activity in the intrahepatic biliary ducts, the extrahepatic biliary ducts, the gallbladder, and the small bowel, ideally within 1 hour after administration of the isotope. Neonatal hepatitis is presumed when there is delayed hepatocyte clearance of the radiopharmaceutical but activity is seen in the small bowel by 24 hours. If the radiopharmaceutical is excreted into the bowel by 24 hours, the diagnosis of biliary atresia is essentially excluded.^{34,42,49} When no radiopharmaceutical is seen in the bowel on the 24-hour delayed images, biliary atresia should be strongly considered (Fig. 119-10). However, nonvisualization of the

Figure 119-10 Biliary atresia: hepatobiliary nuclear scintigram. A. Anterior images of the abdomen and pelvis filmed at 5 minutes/frame demonstrate good uptake of ^{99m}Tc -disofenin by the hepatocytes in the liver (arrow). There is no evidence of activity in the gallbladder, common bile duct, or intestines. Renal uptake (arrowheads) and excretion into the urinary bladder are evident. **B.** Anterior delayed images. After a 2-hour delay, there is persistent activity within the liver and continued clearance by the kidneys (arrowheads) with excreted radiopharmaceutical detected within the urinary bladder (asterisk). The 24-hour image also demonstrates some activity in the liver (arrow) but no evidence of biliary excretion into the small intestine.

radiopharmaceutical in the bowel at 24 hours is not highly specific for biliary atresia because hepatocellular dysfunction in infants with neonatal hepatitis can sometimes be pronounced enough that the radiopharmaceutical is not excreted within the first 24 hours.⁵⁰ The reported diagnostic accuracy of hepatobiliary scintigraphy in the diagnosis of biliary atresia is 56% to 81.6%, with a sensitivity of 91.7% to 100% and a specificity of 35% to 76.9%.^{14,20,42}

For biliary atresia to be excluded, the patency of the common hepatic duct and common duct should be demonstrated,⁴⁹ but this is not always achieved with ultrasound and hepatobiliary scintigraphy. MRCP may eliminate the need in children for more invasive imaging, such as percutaneous transhepatic or intraoperative cholangiography, biopsy, or exploratory surgery, if normal biliary tract anatomy can be demonstrated.¹³ The diagnosis of biliary atresia is made on MRCP when the common bile duct or the common hepatic duct is not visualized.⁴⁹ In infants with cholestatic jaundice, Han and colleagues⁵¹ demonstrated that MRCP had an accuracy of 98%, sensitivity of 100%, and specificity of 96% for the diagnosis of biliary atresia. As on ultrasound, MRCP findings of biliary atresia include nonvisualization of the extrahepatic bile ducts, a small or absent gallbladder, and periportal fibrosis (the triangular cord sign on ultrasound). Periportal fibrosis is often seen as a triangular area of high signal intensity ventral to the porta hepatis on the T2-weighted images^{3,4,49} and as a hypointense signal paralleling the portal vein branches on T1-weighted sequences that becomes isointense with liver after administration of gadolinium.⁵² Gadolinium administration distinguishes the enhancing periportal fibrosis from the nonenhancing, dilated periportal ducts seen in other disease processes.⁵² On T2-weighted images, a focal region of hyperintense signal thought to be fluid has been described within the high signal intensity periportal fibrosis in some children with biliary atresia (Fig. 119-11).⁴

False-positive MRCP results for biliary atresia have been reported; these are in part due to the fact that MRCP relies on the production and excretion of bile into the bile ducts to visualize the biliary tract.¹³ Children with disease states that result in decreased hepatobiliary function and subsequent decreased bile production, such as sclerosing cholangitis, may have false-positive examination findings because the biliary tree is not visualized on MRCP owing to a relative lack of bile within the ducts.^{12,13}

Liver biopsy can help confirm the diagnosis of biliary atresia. An 18-gauge needle biopsy of the liver has been shown to be 90% sensitive, 96% specific,⁴² and 85%¹⁸ to 93%⁴² accurate for the diagnosis of biliary atresia in cholestatic children.⁴² Neonatal hepatitis and early biliary atresia may have identical ultrastructural and light microscopic features.⁵³ If the biopsy is performed early in a particular patient's disease process, the typical ultrastructural features of biliary atresia (i.e., proliferation of the intralobular bile ductules with loss of ductular microvilli, periductal inflammatory fibrosis, and bile plugging) may not yet be present, and a false-negative result may occur.⁵³ If the clinical course and liver biopsy results are not concordant, repeated biopsy may be warranted.

In some children, ultrasound, nuclear scintigraphy, MRCP, and liver biopsy results may all be inconclusive. In these children, visualization of the bile ducts by cholangiography

Figure 119-11 Biliary atresia: MRCP findings. Coronal, thick-slab, T2-weighted image of a 19-day-old infant with cholestasis shows a small focus of increased signal intensity (arrowhead) in the porta hepatis that represents a cystic lesion within the porta hepatis. A gallbladder is identified (arrow), but no linear or branching structures suggesting bile ducts are identified. Lack of identification of the right, left, and main hepatic ducts and common bile duct is consistent with biliary atresia. (Courtesy Myung-Joon Kim, MD, Yonsei University College of Medicine, Severance Hospital, Seoul, Korea.)

intraoperatively, percutaneously through the liver or gallbladder, or by endoscopy may be necessary.

In children with biliary atresia who have undergone the Kasai procedure, it is important to monitor for changes of fibrosis, cirrhosis, and portal hypertension on postoperative imaging. It is also important to know the patient's baseline anatomy and to remember that the loop of jejunum that is anastomosed to the porta hepatis can be seen as a fluid-filled structure, which can be mistaken for a postoperative fluid collection. If necessary, patency of the anastomosis can be confirmed by nuclear scintigraphy.

ALAGILLE'S SYNDROME

Background

Alagille's syndrome, also known as arteriohepatic dysplasia, is a rare autosomal dominant disease characterized by chronic cholestasis due to a paucity of interlobular bile ducts relative to the number of portal areas within the liver.^{54,55} Children with Alagille's syndrome usually present as neonates but may present later.⁵⁶ For diagnosis, at least three of the five typical features of the disease are exhibited: chronic cholestasis from interlobular bile duct paucity, congenital heart disease typically involving hypoplasia or stenosis of the peripheral pulmonary arteries, "butterfly" vertebrae, posterior embryotoxon (an ocular abnormality), and peculiar facies.^{56,57}

Figure 119-12 Nonsyndromic intrahepatic bile duct paucity: ultrasound and hepatobiliary scintigram. **A.** The cholestatic infant has a lack of sonographically identifiable gallbladder or intrahepatic bile ducts. **B.** Nuclear scintigraphy demonstrates poor hepatic extraction (arrows) of the radiopharmaceutical. Some radiopharmaceutical is seen in the urinary bladder (arrowhead). **C** and **D.** There is minimal small bowel activity at 24 hours (arrow). These findings can be seen in the setting of neonatal hepatitis or paucity of intrahepatic bile ducts with cholestasis. Liver biopsy confirmed a paucity of intrahepatic ducts (arrows). This child lacked other clinical abnormalities that are associated with Alagille's syndrome.

Pulmonary artery stenosis at various levels is one of the most common manifestations of Alagille's syndrome. Other associated vascular anomalies include basilar or middle cerebral artery aneurysms, internal carotid artery anomalies, aortic coarctation or aneurysm, and moyamoya syndrome. The intracranial vascular anomalies account for up to 34% of the mortality in these patients.⁵⁷ Renal artery involvement may result in hypertension.⁵⁷

Imaging

The sonographic findings of Alagille's syndrome are similar to those of neonatal hepatitis. In neonatal hepatitis, the liver size and echogenicity may be normal or increased, and the intrahepatic bile ducts are typically not visualized.⁶ Nuclear hepatobiliary scintigraphy may initially resemble biliary atresia⁴⁶ and typically fails to show normal excretion of the radiopharmaceutical into the bowel (Fig. 119-12).⁵⁰ Cholangiography or MRCP should demonstrate patency of the extrahepatic bile ducts, excluding the diagnosis of biliary atresia, but because Alagille's syndrome is rare, this diagnostic step is occasionally foregone, leading to treatment with the Kasai procedure before the pathologic diagnosis of Alagille's syndrome is made.⁵⁶

Biliary cirrhosis occurs in 12% of children with Alagille's syndrome resulting from chronic cholestasis.⁵⁸ Children presenting with Alagille's syndrome at an older age may have findings of cirrhosis. Benign lesions such as nodular hyperplasia have also been described in children with Alagille's syndrome and cirrhosis.⁵⁹ Liver transplantation may ultimately be required.

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS

Background

Progressive familial intrahepatic cholestasis (PFIC) is a group of three slightly distinct autosomal recessive intrahepatic cholestatic disease processes that begin in infancy and progress to cirrhosis, typically within the first decade of life. Children with PFIC present with cholestasis, jaundice, failure to thrive, steatorrhea, pruritus, or rickets.⁶⁰ The average age at onset is 3 months, but some patients may not present until later, even into adolescence. Without treatment, few patients have survived into the third decade of life.⁶¹

The first subtype of what is now known as PFIC was initially identified in Amish descendants of Jacob Byler and was named

Figure 119-13 Choledochal malformation: cystic type. **A** and **B.** Ultrasound images obtained on the third day of life show the small gallbladder (white arrowhead) that empties into the choledochal cyst (arrow). At surgery, the cyst was amputated proximally at the common hepatic duct (black arrowhead).

Byler's disease.⁶² A similar disease was identified in Greenland Eskimo children and was named cholestasis familiaris groenlandica.⁶³ Subsequently, several non-Amish but phenotypically similar patients were reported to have a similar condition, and the broader term Byler's syndrome was adopted.

What were formerly known as Byler's disease and cholestasis familiaris groenlandica have been found to be the same disease and are now grouped into a subtype known as PFIC-1. PFIC-2 is clinically similar to PFIC-1 but primarily occurs in families in the Middle East and Europe. Although both PFIC-1 and PFIC-2 involve life-threatening cholestasis, patients with these diseases have low γ -glutamyl transpeptidase levels. Important clinical features of PFIC-1 include diarrhea, pancreatitis, and hearing loss; PFIC-2 is associated with increased risk of hepatobiliary malignant neoplasms.⁶⁴ Both PFIC-1 and PFIC-2 are caused by the absence of gene products required for canalicular export and bile formation.⁶⁵

Despite a similar clinical presentation, patients with PFIC-3 have elevated levels of serum γ -glutamyl transpeptidase. Rather than defective bile acid export as seen in PFIC-1 and PFIC-2, patients with PFIC-3 have deficient hepatocellular phospholipid export, which leads to unstable micelles that have a toxic effect on the bile ducts, leading to biliary obstruction.⁶⁶

Imaging

Ultrasound findings in patients with PFIC may be normal in the early stages of the disease but will eventually show cirrhosis, including coarsened echotexture, nodular contour, and features of portal hypertension. Nuclear medicine hepatobiliary scintigraphy does not typically have a role in the initial diagnosis of PFIC but is sometimes used after the palliative biliary diversion procedure⁶⁷ to assess for patency.

CHOLEDOCHAL MALFORMATIONS

Background

Choledochal malformations are dilated bile ducts that may be extrahepatic, intrahepatic, or both.³ Choledochal malformations are uncommon, with an estimated incidence of 1 case in 750,000 live births.¹⁸ Choledochal malformations are four to six times more common in girls than in boys.^{68,69}

Infants with choledochal malformations typically present with a palpable abdominal mass that corresponds to an underlying cystic mass (Fig. 119-13), jaundice, and acholic stool.

Figure 119-14 Choledochal malformation: fusiform type on ERCP. There is fusiform dilation of the right and left hepatic ducts (black arrowheads) and their primary intrahepatic branches. The cystic duct (white arrowhead) joins the dilated common hepatic duct to form the common bile duct, and there is an anomalous union of the common bile duct (white arrow) and the pancreatic duct (black arrow). The gallbladder is distended with contrast material (asterisk). No stones are identified.

These children less often have symptoms of vomiting, pain or discomfort, and fever. Children who present with choledochal malformations after 1 year of age have more variable symptoms.

Choledochal malformations are classified morphologically as cylindrical, fusiform (Fig. 119-14), or spindle shaped.⁶⁹ Todani and colleagues⁷⁰ proposed a classification system that

considers the location of the malformation within the biliary tree:

- Type I (most common)
 - A. Dilation of the common bile duct above the level of insertion of the cystic duct
 - B. Dilation of the common bile duct below the level of insertion of the cystic duct
 - C. Diffuse or cylindrical dilation
- Type II. One or more diverticula of the common bile duct
- Type III. Choledochoceles (dilation of the intraduodenal portion of the duct, with both the common bile duct and pancreatic duct emptying into it)
- Type IV. Multiple cysts
 - A. Multiple intrahepatic and extrahepatic ductal cysts
 - B. Multiple extrahepatic ductal cysts only
- Type V (Caroli's disease). Intrahepatic bile duct cyst (single or multiple)

A subtype of Todani type I choledochal malformation (Todani ID) was recently proposed.⁷¹ In addition to dilation of the common hepatic and the common bile duct, this type of choledochal malformation also has dilation of the central portion of the cystic duct, resulting in a bicornal configuration to the malformation.⁷¹

One of the leading theories concerning the cause of choledochal malformations is anomalous union of the pancreatic duct and common bile duct proximal to the ampulla, with subsequent reflux of pancreatic enzymes into the bile ducts.⁷² The pancreatic duct has higher pressure than the common bile duct, and pancreatic fluid may directly reflux into the common bile duct, which is not protected by the choledochal sphincter because the pancreatobiliary malunion occurs outside of the duodenal wall.⁷² This may account for the high level of pancreatic enzymes in the bile within some choledochal malformations.⁶⁹ Choledochal malformations are associated with the following findings: intraductal calculi, intrahepatic biliary dilation, anomalous hepatic biliary ducts, recurrent pancreatitis, and extrahepatic bile duct perforation.^{3,72}

Imaging

Ultrasound is useful in the evaluation for choledochal malformations (see Fig. 119-13).^{2,3,69} Choledochal malformations may be seen on routine prenatal ultrasound (Fig. 119-15).^{12,68} On ultrasound, a choledochal malformation may be seen as a large, lobular, right upper quadrant cystic structure that is distinct

from the gallbladder, extends to the porta hepatis,⁵⁶ and communicates with the biliary ductal system (Fig. 119-16).¹ The intrahepatic ducts are usually normal in caliber and appearance but may be dilated to varying degrees.⁷³

Nuclear hepatobiliary scintigraphy typically confirms the biliary origin of the cystic structure, and the structure can often be distinguished from the gallbladder.⁷⁴ In some patients, the choledochal malformation does not fill with radiopharmaceutical and may cause a photopenic defect in the liver that correlates with sonographic findings.⁷⁴ Additional cross-sectional imaging with MRCP may be a useful adjunct to sonography for preoperative planning.² The need for preoperative ERCP or intraoperative cholangiography, which lengthens operating room time, may be eliminated in the subset of patients in whom MRCP demonstrates the pancreatic duct and the common channel.⁷¹ MRCP can also depict stenosis of intrahepatic ducts or the presence of anomalous hepatic biliary ducts.

The treatment of choledochal malformations in children with persistent or intermittent jaundice is excision of the malformation followed by Roux-en-Y hepaticojejunostomy.¹⁸ In the newborn period, choledochal malformations may be drained externally, followed by excision and biliary reconstruction when the child is older (typically around 5 months old).⁶⁹

There is an approximate 4% risk of malignant transformation in the malformation or the nearby bile or pancreatic duct.⁷⁵ This risk of cancer is approximately 80 times greater than in the general population.⁷⁵ Types of cancer reported include adenocarcinoma, squamous cell carcinoma, and adenoacanthoma.⁷⁰

The differential diagnosis of choledochal malformation includes mesenchymal hamartoma, hepatic cyst, enteric duplication cyst, pancreatic pseudocyst, hepatic artery aneurysm, spontaneous perforation of the common bile duct,¹ and biliary cystadenoma.

CAROLI'S DISEASE

Background

Caroli's disease is also known as Todani type V choledochal malformation^{3,70} and as communicating cavernous ectasia of intrahepatic bile ducts.⁷⁶ Caroli's disease is a rare, congenital disease in which there is segmental nonobstructive dilation of the intrahepatic biliary ducts.⁷⁷ Caroli's disease may affect one or both lobes of the liver, but more commonly the left lobe of the liver is involved.¹⁷ When ectasia is limited to the intrahepatic biliary tree, without other hepatic abnormalities, Caroli's disease

Figure 119-15 Prenatal diagnosis of choledochal malformation. **A.** Prenatal sonogram demonstrates a cystic structure in the periportal region (arrow). The gallbladder (arrowhead) is also identified. **B.** Postnatal sonogram of the same infant on the day of birth confirms the presence of a choledochal cyst (arrows) involving the extrahepatic bile duct. The gallbladder (arrowhead) is identified as a separate structure.

Figure 119-16 Fusiform choledochal malformation.

A and **B**. Sonogram of a 4-year-old child with recurrent pancreatitis. The images demonstrate fusiform dilation of the intrahepatic (**A**, arrows) and extrahepatic (**B**, arrow) bile ducts. **C**. ERCP shows fusiform dilation of the common bile duct (white arrowhead) and the common hepatic duct and its primary branches. The gallbladder (asterisk) is identified. There is an irregularity of the pancreatic duct (black arrowheads) that has an anomalous insertion into the common bile duct. **D**. The common pancreaticobiliary channel (arrowheads) contains a 5-mm stone (arrow).

is the term used. Caroli's syndrome, which is more common than Caroli's disease, involves ectasia of small and large bile ducts and is associated with congenital hepatic fibrosis. Periportal fibrosis can lead to cirrhosis and portal hypertension in patients with Caroli's syndrome.^{77,78}

Both Caroli's disease and Caroli's syndrome are transmitted in an autosomal recessive manner. There is an association between Caroli's disease and Caroli's syndrome and renal cystic diseases, including autosomal recessive polycystic kidney disease (Fig. 119-17), renal tubular ectasia, medullary sponge kidney, and nephronophthisis with cysts in the renal medulla and corticomedullary junction.^{3,73}

One of the most accepted theories regarding the pathogenesis of Caroli's disease is that it results from arrest during remodeling of the embryonic ductal plate. The ductal plate is a sleeve-like layer of hepatic precursor cells (hepatoblasts) that surrounds the portal venous branches. The ductal plate cells duplicate and separate, creating a slitlike lumen between the two

epithelial layers. The ductal plate remodels throughout fetal life to form the intrahepatic bile ducts. Incomplete remodeling is thought to result in a ductal plate malformation and eventually Caroli's disease.⁷⁸

Most patients with Caroli's disease or Caroli's syndrome present during childhood or as young adults with fever, recurrent or crampy abdominal pain, and transient jaundice.^{1,79} These presenting symptoms result from bile stasis and stone formation.⁷⁹ Young children may present with recurrent abdominal pain, pruritus, acholic stools, and intermittent jaundice. The liver may be enlarged.⁷⁹

Cholangiocarcinoma has been reported in up to 7% of people with congenital cystic dilation of the intrahepatic bile ducts,⁷⁷ which is more than 100 times greater than in the general population.⁶⁷ The cause of the malignant transformation is unknown. Early diagnosis of malignant transformation is difficult because the symptoms may mimic cholangitis.⁷⁷

Figure 119-17 Caroli's disease: MR features. **A.** Axial view, T1-weighted MR image demonstrates diffuse intrahepatic bile duct dilation with scattered areas of saccular dilation (arrowheads). **B.** Axial view, T2-weighted MR image of the kidneys. The kidneys (arrows) are diffusely enlarged without hydronephrosis. The constellation of findings is consistent with Caroli's disease with associated autosomal recessive polycystic kidney disease.

Imaging

Sonographic findings in Caroli's disease include ectatic intrahepatic bile ducts with echogenic septa that completely or incompletely traverse the dilated duct lumen and small portal venous branches that are partly or completely surrounded by the dilated bile ducts.⁸⁰ On CT, the centrally enhancing portal radicle surrounded by the low-attenuation, dilated bile ducts is called the central dot sign.⁴³

BILE PLUG SYNDROME OR INSPISSATED BILE SYNDROME

Inspissated bile is the second most common cause of surgically treatable neonatal jaundice after biliary atresia. It is slightly more common than choledochal malformation.¹⁸ Ultrasound may show a dilated common bile duct with a normal-appearing gallbladder. The occluding bile plug is evident sonographically in 30% of children.¹⁸ Inspissated bile is slightly hyperechoic and does not cause acoustic shadowing. A fluid-debris level may be seen in the dilated obstructed bile duct.¹ Sludge can be isoechoic with the liver, and if it fills the gallbladder lumen, it may make the gallbladder difficult to visualize.⁶ The hepatic echotexture may be increased because of cholestasis.¹

The diagnosis can be confirmed by percutaneous transhepatic cholangiography and treated during the procedure with therapeutic saline lavage of the biliary tree. Postprocedural follow-up ultrasounds shows return of the bile ducts to normal caliber.¹⁸

Gallbladder Disease

CHOLELITHIASIS

Gallstones can be seen in children of any age (Fig. 119-18).⁸¹ The classic risk factors for cholelithiasis in children include hemolysis, prior gastrointestinal surgery, and total parenteral nutrition.⁸²⁻⁸⁴ In neonates and infants, additional proposed risk factors include prematurity, prolonged fasting,⁸⁴ and furose-mide treatment.^{82,85} Stones have also been found in newborns and infants with a history of septicemia, hyperbilirubinemia requiring phototherapy, and intestinal malabsorption.⁸⁶ In

Figure 119-18 Neonatal gallstone. Ultrasound image of a 1-day-old infant (gestational age of 37 weeks) demonstrates a gallstone (arrowhead) and sludge (arrow) within the gallbladder.

older children, the causes of biliary stones are numerous and include sickle cell disease,⁸⁷ total parenteral nutrition, ileal resection, hemolytic anemia, and cystic fibrosis.^{88,89} The rate of cholelithiasis in children with sickle cell disease increases with advancing age, up to 42% in the 15- to 18-year-old age group.⁸⁷ In the adolescent population, cholelithiasis is associated with pregnancy,^{84,89} use of birth control pills, and obesity.⁸⁴ The imaging features of gallstones are described in Chapter 77.

ACALCULOUS CHOLECYSTITIS

Acalculous cholecystitis is inflammation of the gallbladder without gallstones. Acalculous cholecystitis is considered acute if the symptoms are present for less than 1 month or chronic if the symptoms persist for longer than 3 months.⁹⁰

The symptoms of acalculous cholecystitis include fever, jaundice, abdominal pain, right upper quadrant pain, and

Figure 119-19 Acute acalculous cholecystitis: sonographic findings. The gallbladder wall is diffusely thickened (arrowheads). The tiny, hypoechoic lumen is free of stones (arrow).

vomiting.^{84,90} Most children with acute acalculous cholecystitis also have leukocytosis and abnormal liver function test results. Acute acalculous cholecystitis is most often seen in the immediate postoperative period or in association with a systemic medical illness, severe trauma, burns, metabolic illness, multiple transfusions, intravenous narcotic use, or hyperalimentation.⁹⁰ *Salmonella* sepsis should also be considered an infectious cause in children.⁸² Acute acalculous cholecystitis can be treated medically or with cholecystectomy.⁹¹

On ultrasound, the gallbladder is free of stones, although it may contain sludge, may be distended, and may have a thick wall (Fig. 119-19).^{73,81} This wall thickening may be caused by edema or focal hemorrhage.⁸¹ Chronic cholecystitis in children is more often associated with cholelithiasis.⁷³

GALLBLADDER DYSKINESIA

Gallbladder dyskinesia is characterized by poor gallbladder contractility. Children and adolescents with this disorder have chronic abdominal pain. A ^{99m}Tc hepatobiliary scan, followed with cholecystokinin injection to induce gallbladder contraction, may be diagnostic. An ejection fraction of less than 35% is considered abnormal.⁸⁴

Rescorla⁷³ reported that 20% of children undergoing laparoscopic cholecystectomy had a preoperative diagnosis of biliary dyskinesia. In that series, pathologic evaluation revealed changes of chronic cholecystitis in 71%, but 93% were relieved of their pain after cholecystectomy.

GALLBLADDER HYDROPS

Hydrops of the gallbladder is abnormal distention of the gallbladder without gallbladder wall thickening or inflammation.⁹² The bile within the gallbladder may be abnormally thick and transiently obstruct the cystic duct,⁹³ or the obstruction may be extrinsic,⁶ possibly caused by enlarged periportal lymph nodes.⁹³

Figure 119-20 Gallbladder hydrops. The gallbladder is abnormally distended, measuring more than 10 cm long in this 22-month-old child after bone marrow transplantation. The gallbladder wall is thin (arrows), and there is echogenic sludge within the lumen. The gallbladder was later drained with a cholecystostomy tube.

Vasculitis can also be a causative factor in gallbladder hydrops.⁶ After the initial obstruction, the gallbladder is further distended by serous fluid secreted by the gallbladder mucosa.⁶ Bowen argues that the transient, acute distention of the gallbladder occurring in infants who are not fed or in those with acute obstruction of the cystic duct is “transient gallbladder dilation” and that the term *hydrops* may best be reserved for cases in which the cystic duct is obstructed so long that bile within the gallbladder is replaced by clear, thin, colorless liquid.⁹³

Hydrops of the gallbladder is typically caused by bile stasis resulting from dehydration or prolonged fasting.⁶ Neonatal hydrops can be seen in the setting of infection or hyperalimentation.^{92,93} In older children, there is a reported association with mucocutaneous lymph node syndrome (Kawasaki’s syndrome) and a variety of infections.⁹³ Presentation may include jaundice, abdominal distention, and a palpable right upper quadrant mass,^{92,93} but it may be asymptomatic.⁶

In acute hydrops, the ultrasound measurement of the gallbladder length is more than 3 cm in infants and more than 7 cm in older children.⁶ The wall is not thickened, and there may or may not be sludge (Fig. 119-20); the biliary tract is otherwise not abnormally dilated.⁶

Bile Duct Disease

CHOLEDOCHOLITHIASIS

Gallbladder stones and choledocholithiasis coexist in up to 13% of children with cholelithiasis requiring cholecystectomy.^{84,94} The common duct stones are spontaneously passed without the need for routine preoperative or postoperative ERCP in most children.⁹⁴ However, complete obstruction of

Figure 119-21 Common bile duct stone or sludge: sonographic features. **A.** The common bile duct (arrowheads) is abnormally dilated and contains hyperechoic stones, sludge, or both (arrows). **B.** The gallbladder is grossly distended with sludge (asterisk) in this 8-year-old child with sickle cell disease.

the biliary tract or pancreatitis can occur.^{84,94} In a series by Vrochides and colleagues,⁹⁴ 11 of 12 children undergoing cholecystectomy who had an intraoperative cholangiographic diagnosis of choledocholithiasis were asymptomatic postoperatively, even without surgical removal of the intraductal stones. One-week follow-up sonography demonstrated no stones or evidence of obstruction. In children, postoperative ERCP with sphincterotomy and stone removal are warranted in the unusual circumstance of symptomatic postoperative retention of common bile duct stones.⁹⁴

Ultrasound is accurate in the detection of calculi within the gallbladder but less so in the intrahepatic and extrahepatic ducts.³ Choledocholithiasis appears sonographically as a brightly echogenic, shadowing structure within the biliary ducts, often with proximal ductal dilation (Fig. 119-21).¹

MRCP in adults has been reported to have 95% sensitivity, 100% specificity, 100% positive predictive value, and 98% negative predictive value for diagnosis of choledocholithiasis.⁹⁵ MRCP evaluation of choledocholithiasis has not been extensively studied in children.³

BILIARY CHANGES WITH CYSTIC FIBROSIS

In addition to the hepatic fibrosis and cirrhosis, patients with cystic fibrosis may develop biliary disease, including cholelithiasis and bile sludge formation.^{88,89} Gallstones (usually cholesterol) occur in approximately 10% of patients with cystic fibrosis.⁹⁶ Neonates with cystic fibrosis may have prolonged jaundice related to inspissated bile.⁹⁶

Ultrasound and MRCP are used as noninvasive tools to assess for these changes.⁹⁷ On sonography, a thick-walled, tiny gallbladder can be seen in children with cystic fibrosis.⁹ Although approximately one in three patients with cystic fibrosis has a small gallbladder, gallbladder function is usually normal.⁹⁶ Some children have painful focal bile ductule stenosis, which is manifested as delayed excretion of radiopharmaceutical on hepatobiliary scintigraphy.⁹⁶ MRCP can be used to assess the biliary tract in addition to evaluating patients for the typical pancreatic, hepatic, and splenic abnormalities associated with cystic fibrosis.⁹⁷ These findings include a tiny gallbladder with or without stones; intraductal cholelithiasis; intrahepatic and extrahepatic bile duct strictures; duct wall irregularity; and areas of duct dilation, which in some cases result in a beaded appearance.⁹⁷

Historically, 23% of cystic fibrosis patients at autopsy have gallbladders of abnormal size or with abnormal contents, without inflammatory changes.⁹⁸ The gallbladder may be hypoplastic, atrophied, or dilated, and there may be numerous, epithelial cell-lined, multiloculated, mucoid-containing “cysts” in and just below the mucosa. The gallbladder lumen may contain clear or gray mucus rather than bile.⁹⁸

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is a chronic progressive disorder that involves inflammation, fibrosis, and subsequent stricturing of medium and large intrahepatic and extrahepatic biliary ducts. Most children have intrahepatic and extrahepatic involvement, although the disease may be limited to either site.⁹⁹ PSC may affect only isolated areas of the intrahepatic bile ducts, unlike Caroli's disease, in which the large central intrahepatic ducts are typically affected.⁷⁶

Most children with PSC are symptomatic at the time of diagnosis and present with abnormal liver function test results and one or more of the following signs or symptoms: abdominal pain, fatigue, jaundice, splenomegaly with or without hepatomegaly, ascites, fever, and weight loss.^{99,100} As many as 81% of the children have associated inflammatory bowel disease, typically ulcerative colitis.⁹⁹ Other children have comorbid extrabiliary disease, such as Langerhans cell histiocytosis, immunodeficiency,¹⁰⁰ systemic lupus erythematosus, insulin-dependent diabetes mellitus, or autoimmune thyroiditis.⁹⁹ Thirty-five percent of the children with PSC also have histologic features consistent with autoimmune hepatitis.⁹⁹ Many children with PSC progress to end-stage liver disease and require liver transplantation. PSC may recur in the allograft.⁹⁹

Sonographic findings of sclerosing cholangitis include dilated intrahepatic and, less often, extrahepatic bile ducts,¹⁰⁰ bile duct wall thickening, intrahepatic and extrahepatic duct stones, gallstones, and segmental ductal narrowing due to strictures. The strictures may be difficult to detect unless there is also duct dilation.⁶ There may be signs of cirrhosis or portal hypertension.¹⁰⁰ MRCP or conventional cholangiography may show intrahepatic or extrahepatic bile duct wall irregularity, long- or short-segment strictures, filling defects, and abnormal dilations with or without interpositional annular strictures (Fig. 119-22).¹⁰⁰ The imaging features of PSC are discussed further in Chapter 80.

Figure 119-22 Sclerosing cholangitis: ERCP findings. **A.** ERCP image of a teen with Crohn's disease and sclerosing cholangitis. There are filling defects within the ducts that may represent stones (arrowheads). Segmental narrowing or strictures (arrows) are present throughout the intrahepatic bile ducts. (Courtesy Lisa Lowe, MD, Children's Mercy Hospital and Clinics, University of Missouri, Kansas City, MO.) **B.** ERCP image of a 9-year-old child with ulcerative colitis and sclerosing cholangitis. Arrowheads mark the intraluminal filling defects, which are probably calculi. There are multiple filling defects within the gallbladder (asterisk), and there is mild duct wall irregularity (arrows) without significant stricture formation. (Courtesy Laura Z. Fenton, MD, The Children's Hospital and University of Colorado Health Sciences, Denver, CO.)

Figure 119-23 Biliary obstruction by a pancreatic head neoplasm. **A.** The large, mixed density mass with a thick wall (arrowheads) originating in the pancreatic head is a solid and papillary epithelial neoplasm of the pancreas in this 2-year-old child. **B.** The mass is obstructing the common bile duct, and there is subsequent intrahepatic bile duct dilation (arrows). (Courtesy Laura Z. Fenton, MD, The Children's Hospital and University of Colorado Health Sciences, Denver, CO.)

Neoplasms

Extrahepatic neoplasms, such as pancreaticobiliary lymphoma, can create mass effect on the bile ducts. Intraductal neoplasms, such as rhabdomyosarcoma, also result in biliary obstruction. Presenting symptoms include anorexia, jaundice, itching, fever, abdominal distention (with or without pain), vomiting, and a palpable abdominal mass.¹⁰¹⁻¹⁰³ Mass effect from tumors such as biliary rhabdomyosarcoma,¹⁰¹ lymphoma,¹⁰² pancreatic head neoplasm such as hemangioendothelioma,¹⁰⁴ and pancreatic adenocarcinoma with extension to the common bile duct¹⁰⁵ has been reported to cause obstructive jaundice (Fig. 119-23).¹⁰²

Rhabdomyosarcoma is the only primary neoplasm to arise within the pediatric biliary tree.¹⁰⁶ It is typically the embryonal variety (i.e., sarcoma botryoides).^{103,107} Rhabdomyosarcoma may arise from the ampulla,¹⁰¹ common bile duct,¹⁰³ or hepatic

ducts.¹⁰⁷ Most children present with intermittent jaundice, fever, and anorexia with or without abdominal distention.¹⁰³ Ultrasound may demonstrate a mass in the porta hepatis.¹⁰³ On CT, the soft tissue mass is seen distending the affected bile ducts (Figs. 119-24 and 119-25).¹⁰⁶ There may be secondary intrahepatic duct dilation. CT may also show retroperitoneal and mesenteric lymphadenopathy.¹⁰⁶ The tumor may extend into the liver. Metastases to regional nodes, peritoneum, and omentum occur in 30% of the children.¹⁰³ Pediatric ampullary rhabdomyosarcoma has been successfully treated by pancreaticoduodenectomy with adjuvant chemotherapy, irradiation, or both.¹⁰¹

Pancreaticobiliary lymphoma can involve the porta hepatis and the gallbladder without causing obstruction.¹⁰² The lymphomatous masses that do obstruct the biliary tree often respond quickly to chemotherapy and may not require a biliary drainage procedure.^{102,108,109}

Figure 119-24 Biliary rhabdomyosarcoma. **A.** Contrast-enhanced CT of a 2-year-old child with fever, malaise, and jaundice. The arrows indicate the dilated intrahepatic bile ducts. In one area, there is a higher attenuation substance that may represent intraluminal sludge or an intraductal mass (arrowhead). **B.** Intraoperative cholangiogram obtained by injection of contrast material into the gallbladder (asterisk) demonstrates multiple filling defects (arrowheads) within the dilated bile ducts, including the common bile duct. The bile ducts proximal to the intraductal masses are also dilated (arrows). Surgical biopsy confirmed the diagnosis of embryonal rhabdomyosarcoma. (From Donnelly LF, Bisset GS III, Frush DP: Case 2: Embryonal rhabdomyosarcoma of the biliary tree. *Radiology* 208:621–623, 1998.)

Figure 119-25 Biliary rhabdomyosarcoma. **A.** Ultrasound image of the liver in a 3-year-old child with malaise and jaundice shows dilated intrabiliary ducts (arrows). **B.** Coronal T2-weighted MRCP image from the same patient. The arrows indicate the dilated intrahepatic bile ducts and common hepatic duct. Extensive tumor involvement is seen in the common bile duct (asterisk).

Cystic Fibrosis

Glycogen Storage Diseases

Gaucher's Disease

Liver disease is less common in the pediatric population than it is in the adult population, but the sequelae can be equally devastating and may lead to the need for liver transplantation. This chapter addresses the more common congenital, neoplastic, infectious, vascular, and metabolic disorders of the pediatric liver.

At birth, the liver occupies approximately 40% of the abdominal cavity and represents 5% of the infant's total body weight. The relative size of the liver to the abdominal cavity decreases as a child grows. During infancy, the inferior hepatic margin is normally several centimeters below the costal margin, but it becomes less prominent throughout childhood.

Imaging of the pediatric liver may be prompted by hepatomegaly, abnormal liver function test results, jaundice, a palpable mass, or an abnormality detected on prenatal ultrasound. Imaging also plays an important role in evaluation of the liver before and after liver transplantation. This chapter focuses on liver masses and diseases that are unique to the pediatric population, particularly when the imaging approach diverges from that used in the adult population.

Imaging Approach for a Suspected Hepatic Mass

A palpable abdominal mass is the most common clinical presentation in a child with a liver mass. Other frequently encountered presenting signs and symptoms include hepatomegaly, abdominal pain, weight loss, anorexia, jaundice, and paraneoplastic syndromes. In addition, large vascular malformations may be manifested as congestive heart failure or consumptive coagulopathy (Kasabach-Merritt syndrome). Ultrasound is a useful imaging modality in the work-up of a suspected liver mass in a child because it allows evaluation of the abdominal viscera and vasculature. Ultrasound is relatively inexpensive, does not expose the child to ionizing radiation, and usually does not require that the patient be sedated. When an abdominal mass is identified, ultrasound can help determine the organ of origin, whether the mass is cystic or solid, if there is vascular flow to the mass, whether the mass contains calcifications, and involvement of other abdominal organs.

After the presence of a liver mass is confirmed by ultrasound, additional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is usually performed. Because surgical resection is the first line of treatment for many pediatric liver masses, precise anatomic delineation of the mass is important. The decision to pursue CT or MRI as the subsequent imaging modality is often driven by institutional and individual preferences because each modality has its own strengths and limitations. MRI is often preferred because it provides detailed multiplanar anatomic information, does not rely on proper timing of bolus contrast material administration for delineation of the vasculature, and imparts no ionizing radiation. CT is often more readily available than MRI and less commonly requires sedation.

When focal nodular hyperplasia is a consideration, technetium Tc 99m sulfur colloid scintigraphy may be a helpful adjunct study. Focal nodular hyperplasia demonstrates normal to increased uptake of the radiopharmaceutical, whereas other hepatic masses create photopenic areas. Tagged red blood cell studies can also be helpful in differentiating hemangiomas from other masses in the liver; hemangiomas demonstrate increased radiopharmaceutical activity, whereas other hepatic masses do not.

Congenital Anomalies**MALFORMATIONS AND HERNIAS**

The major congenital malformations of the liver include anomalous lobar development, lobar hypoplasia, and complete lobar agenesis. Agenesis and hypoplasia of the liver most commonly involve segment IV in the left lobe and segments V and VIII in the right lobe.¹ The best diagnostic clue, besides obvious absence of liver parenchyma, is absence of the respective hepatic and

portal veins and intrahepatic biliary ducts.¹ With congenital agenesis or hypoplasia of a lobe of the liver, compensatory enlargement of the remaining hepatic parenchyma usually occurs. Hepatic agenesis is associated with biliary tract disease, portal hypertension, and other congenital anomalies.² Herniation of the liver parenchyma through a diaphragmatic hernia is typically present at birth but may be delayed. For example, group B streptococcal pneumonia has been associated with late-onset, right-sided diaphragmatic hernia.³

FIBROPOLYCYSTIC DISEASES OF THE LIVER

Fibropolycystic diseases of the liver are thought to be the sequelae of ductal plate malformations, which involve partial or total arrest of remodeling of the ductal plate and result in persistence of embryonic biliary structures.⁴ Ductal plate malformations may involve segmental bile ducts (large), interlobular bile ducts (medium sized), or the smallest bile duct ramifications, resulting in distinct disease entities. Choledochal malformations (extrahepatic) and Caroli's disease (intrahepatic) involve malformations of large embryologic hepatobiliary ducts. Autosomal dominant polycystic liver disease (ADPLD) involves malformations of medium-sized embryologic hepatobiliary ducts. Fibropolycystic liver diseases involving malformations of small embryologic hepatobiliary ducts include congenital hepatic fibrosis and biliary hamartomas (von Meyenburg complexes).⁵ Caroli's syndrome (Caroli's disease with congenital hepatic fibrosis) involves large and small biliary ducts.⁶

Choledochal malformations (also known as choledochal cysts) and Caroli's disease (also known as type V choledochal cyst) are characterized by dilated extrahepatic and intrahepatic bile ducts, respectively, and are thought to happen during early bile duct embryogenesis. A second widely accepted theory of development of choledochal malformations is abnormal proximal insertion of the pancreatic duct into the common bile duct, which causes reflux of pancreatic enzymes into the common bile duct that weaken the duct wall and results in abnormal dilation.^{7,8} Caroli's disease and choledochal malformations, their diagnostic work-up, and imaging findings are discussed in Chapter 119.

ADPLD involves malformations of medium-sized bile ducts and is associated with autosomal dominant polycystic kidney disease (ADPKD) (Fig. 120-1). ADPLD is very rarely seen

without ADPKD. The development of liver cysts usually occurs after the development of renal cysts, and because renal cysts in ADPKD typically are not manifested until the second or third decade of life, ADPLD rarely is manifested in childhood. ADPLD is manifested in 29% to 48% of people with ADPKD.⁹ Hepatomegaly is usually the first indication that there may be underlying polycystic liver disease. Ultrasound, CT, MRI, and magnetic resonance cholangiopancreatography (MRCP) are useful in the detection of cysts in the liver. Ultrasound demonstrates multiple anechoic, thin-walled lesions, with posterior acoustic enhancement. On CT, the hepatic cysts are fluid attenuation; on MRI and MRCP, the cysts are hypointense on T1-weighted sequences and hyperintense on T2-weighted sequences. If there has been hemorrhage into the cysts, prior infection, or other reasons that the fluid may be more complex, the echogenicity, attenuation, and signal will change accordingly.^{5,10}

Congenital hepatic fibrosis involves defective remodeling of the smaller interlobular bile ducts and is characterized by abnormal branching of the intrahepatic portal veins and progressive fibrosis of the portal tracts.¹¹ Congenital hepatic fibrosis may occur with or without macroscopically visible cystic dilations of the intrahepatic biliary ducts. Congenital hepatic fibrosis with macroscopic liver cysts that communicate with the biliary ducts (also known as Caroli's disease) is referred to as Caroli's syndrome. Caroli's disease is much rarer than Caroli's syndrome. Caroli's disease and Caroli's syndrome can occur in different members of the same family, suggesting that these two disease entities may be on the same continuum. Congenital hepatic fibrosis sometimes is manifested in early childhood but may not be manifested until later in life.

Congenital hepatic fibrosis and Caroli's syndrome are associated with fibrocystic renal disease, including autosomal recessive polycystic kidney disease (ARPKD) and ADPKD; glomerulocystic kidney disease; diffuse cystic dysplastic kidneys; tubulointerstitial disorders, such as nephronophthisis, chronic tubulointerstitial disease, and urine-concentrating defect; and medullary sponge kidney (a radiologic term for microcystic dilations of renal collecting ducts on contrast-enhanced imaging that may be seen with or without nephrocalcinosis). All patients with ARPKD who survive the neonatal period develop clinical findings of congenital hepatic fibrosis.¹² Nonobstructive dilation of the intrahepatic bile ducts in the liver (Caroli's disease) is seen at the histologic level in a subset of patients as well.¹²

Figure 120-1 Autosomal dominant polycystic kidney disease. A. CT scan through the upper abdomen reveals multiple, small renal cysts. B. Numerous, small liver cysts are seen better on a higher section.

On ultrasound, patients with congenital hepatic fibrosis may have normal or increased parenchymal echogenicity, normal or coarsened parenchymal echotexture, hyperechoic portal triads, or poorly defined portal vessels. Cysts may be seen in the parenchyma, and the left lobe of the liver may be enlarged; there may be signs of portal hypertension, including reversal of flow in the portal vein, splenomegaly, and varices.¹³ Because of the association with fibrocystic kidney disease, the kidneys may be abnormal as well, and evaluation with a high-frequency transducer may be useful for detailed evaluation of the renal parenchyma. On CT, the liver is heterogeneous in attenuation, the left lobe of the liver is enlarged, and the associated findings of portal hypertension and fibrocystic renal disease may be evident. Findings of congenital hepatic fibrosis on MRI include hypointense signal in the liver parenchyma on T1- and T2-weighted sequences with hyperintense signal within the portal vessels on T2-weighted imaging (which reflects the periportal fibrosis), enlarged spleen, and accompanying fibrocystic changes in the kidneys.¹³ When associated Caroli's disease is present, MRCP may reveal cystic or fusiform dilations and irregularities of the intrahepatic bile ducts.¹⁴ Complications of congenital hepatic fibrosis include ascending cholangitis, sequelae of portal hypertension including cirrhosis and variceal bleeding, and increased risk of hepatocellular carcinoma.¹⁴

Biliary hamartomas (also known as biliary microhamartomas or von Meyenburg complexes) are also thought to be due to small interlobular ductal plate malformations. Biliary hamartomas can be confused with metastatic disease, and therefore definite diagnosis requires a tissue sample. On ultrasound, biliary hamartomas may be hypoechoic or hyperechoic. On CT, biliary hamartomas typically are uniform in size and do not enhance.¹⁴ On MRI, biliary hamartomas are typically hypointense on T1-weighted sequences and hyperintense on T2-weighted sequences.¹⁴

HEPATIC CYSTS

Hepatic cysts are thought to represent growth arrest and dilation of the biliary tract, although there is some support for a theory of vascular insult leading to necrosis and cyst formation (Fig. 120-2). They may be detected prenatally, but a definitive

Figure 120-2 Hepatic cyst. A simple liver cyst in a 6-month-old infant was initially detected on prenatal ultrasound. Continued enlargement led to additional imaging and surgical resection.

diagnosis may not be possible until after birth. Differential diagnosis for peripheral lesions includes cystic hepatoblastoma, mesenchymal hamartoma, and vascular malformation. When the cyst has a subhepatic location, choledochal cyst, pancreatic pseudocyst, alimentary duplication, mesenteric cyst, and urachal cyst are additional considerations.¹⁵

Malignant Hepatic Neoplasms

In children, hepatic masses are relatively uncommon, accounting for 5% to 6% of all abdominal masses in the pediatric population.¹⁶ Primary neoplasms of the liver represent only 0.5% to 2% of all childhood malignant neoplasms, but they are by far the most common primary malignant neoplasms of the pediatric gastrointestinal tract. Primary hepatic neoplasms are the third most common abdominal malignant neoplasm in childhood, after Wilms' tumor and neuroblastoma.¹⁷

PRIMARY MALIGNANT NEOPLASMS

No hepatic malignant neoplasm has imaging features so pathognomonic as to obviate tissue diagnosis.^{17,18} The primary purpose of imaging is to characterize the lesion and to define the extent of disease relative to segmental anatomy, vascular structures, and the biliary system for potential chemotherapeutic intervention and preoperative planning.^{19,20} Follow-up imaging is necessary for assessment of tumor response to treatment protocols and determination of the potential for resection. Most malignant pediatric liver tumors require complete resection or transplantation as a prerequisite for cure.²¹

Hepatoblastoma, hepatocellular carcinoma, and the less frequently encountered embryonal sarcoma account for approximately two thirds of primary malignant hepatic tumors in children. The remaining primary tumors of the liver are uncommon in children and include fibrolamellar hepatocellular carcinoma, angiosarcoma, epithelioid hemangioendothelioma (a very rare tumor that is on the continuum between angiosarcoma and hemangioma), rhabdoid tumor, endodermal sinus tumor, and lymphosarcoma. Embryonal rhabdomyosarcoma is the most common malignant neoplasm to arise from the biliary tract in children and is discussed in Chapter 119.²²

Hepatoblastoma

Hepatoblastoma is the most common pediatric hepatic malignant neoplasm, accounting for 1% of all pediatric malignant neoplasms.²³ Hepatoblastomas are embryonal tumors derived from pluripotent stem cells with the capability of differentiating into hepatocytes and biliary epithelial cells. On histologic examination, these tumors are classified as epithelial, mixed (i.e., epithelial and mesenchymal), or anaplastic type. The epithelial type is the most common, accounting for approximately 60% of all hepatoblastomas.²⁴⁻²⁶ The epithelial type is further subdivided into fetal and embryonal forms. Pure fetal histology carries a better prognosis, and anaplastic or undifferentiated histology carries a poorer prognosis. With the mixed-type tumors, the presence of mesenchymal components carries a more favorable prognosis. The most commonly found mesenchymal components are cartilage and osteoid.^{24,25}

Hepatoblastoma usually occurs in infants and children younger than 3 years, with a median age of occurrence of approximately 1 year. This tumor is slightly more common in boys than in girls, with a male-to-female ratio of approximately

3:2.²⁷ No environmental risk factors have been definitively linked to hepatoblastoma, but an increased incidence of hepatoblastoma has been reported in infants with prematurity or low birth weight.^{28,29} Hepatoblastomas occurring within families have also been reported, with increased risk in children with Beckwith-Wiedemann syndrome and familial adenomatous polyposis. The association between hepatoblastoma and these two syndromes suggests that aberrations of chromosomes 11 and 5 play a role in pathogenesis.^{30,31} Several other conditions that demonstrate an increased incidence of hepatoblastoma are hemihypertrophy, Wilms' tumor, and biliary atresia.

Hepatoblastoma usually is manifested as a painless abdominal mass, but weight loss, anorexia, abdominal pain, jaundice, and rarely precocious puberty may be present. Most patients have no underlying liver disease. On occasion, levels of human β -chorionic gonadotropin are elevated, producing virilization and moderate thrombocytosis. Serum α -fetoprotein levels are elevated in more than 90% of children with hepatoblastoma. In a child younger than 3 years with a liver mass and an elevated α -fetoprotein level, hepatoblastoma should be the primary consideration.

The most common site of involvement of hepatoblastoma is the right lobe of the liver, although bilateral disease is seen in approximately 35% of cases (Figs. 120-3 and 120-4).³¹ Distant metastases are present in 20% of patients at the time of diagnosis, most commonly within the lungs.²⁹ On pathologic examination, hepatoblastomas have a tendency to be pseudo-encapsulated, well defined, and large at the time of presentation. On average, these liver masses are 10 to 20 cm in diameter at presentation.^{25,32} Hepatoblastoma commonly appears sonographically as a well-circumscribed, predominantly echogenic, solid mass.³³ Calcifications are apparent by ultrasound in up to one third of patients and are manifested as punctuate heterogeneous hyperechoic areas with posterior shadowing. Rarely, hepatoblastomas are cystic.³⁴

CT usually demonstrates a large, hypoattenuating, well-defined mass with homogeneous enhancement after the intravenous administration of contrast material (Fig. 120-5). CT better defines calcifications than ultrasound or MRI.

Calcifications tend to be punctate and delicate in epithelial-type tumors, but they are more often extensive and coarse in the mixed-type tumors.³⁵ MRI most commonly depicts a well-defined hepatic mass that is hypointense on T1-weighted sequences and hyperintense on T2-weighted sequences.^{25,35} When necrosis or hemorrhage exists within the tumor, there may be regions of hyperintense T1-weighted signal within the mass. Contrast-enhanced CT and MRI readily depict invasion, encasement, or thrombosis of the main portal vein or the hepatic artery. The presence or absence of these findings strongly affects tumor resectability.³⁶ The advent of combined adjuvant and neoadjuvant chemotherapy, hepatic resection, and, in some cases, liver transplantation has led to a dramatic improvement in survival. The 5-year survival rate for children with hepatoblastoma is 75%.³⁷

Figure 120-4 Multifocal hepatoblastoma. Contrast-enhanced CT demonstrates multiple, low-attenuation hepatic masses and thrombosis of the portal vein in a 1-year-old child.

Figure 120-3 Hepatoblastoma. Contrast-enhanced CT through the upper abdomen in a 6-month-old child reveals a large isoattenuating mass arising from the medial segment of the left hepatic lobe.

Figure 120-5 Hepatoblastoma. A 3-year-old boy presented with an abdominal mass. Contrast-enhanced CT demonstrates a low-density, well-margined mass in the right lobe of the liver.

Hepatocellular Carcinoma

Hepatocellular carcinoma is rare in childhood, accounting for approximately 0.5% of all pediatric malignant neoplasms. After hepatoblastoma, hepatocellular carcinoma is the second most common primary hepatic tumor of childhood and the most common primary liver tumor in children older than 4 years.^{37,38} Histologic features of hepatic cellular carcinoma in children are similar to those in adults, with tumor cells that closely resemble hepatocytes. Tumor growth varies, but these lesions often are manifested as multicentric, diffuse, or infiltrative masses.³⁹ If necrosis is present, portions of the tumor may appear cystic. Hepatocellular carcinoma occurs more commonly in boys and older children. It has a bimodal age distribution. The first peak occurs at age 4 to 5 years, and the second peak occurs at age 12 to 14 years. The mean age at diagnosis is 12 years.⁴⁰

Although histologic and gross specimen characteristics follow the patterns seen in adults, the underlying causes in children are for the most part unique: biliary atresia, Fanconi anemia, hepatitis B viral infection, familial cholestasis, hereditary tyrosinemia, and glycogen storage disease type 1A. Glycogen storage disease type 1A results from a deficiency of glucose-6-phosphatase and leads to the development of hepatic adenomas in approximately 50% of patients. These patients are also at risk for hepatocellular carcinoma from malignant transformation of existing adenomas or from development of new tumors.^{41,42} Hyperalimentation, treatment with androgenic steroids or methotrexate, and use of oral contraceptives are also associated with an increased risk for hepatocellular carcinoma.⁴³ More than 50% of children with hepatocellular carcinoma have no preexisting liver disease or other risk factors, however.^{39,44} Many pediatric hepatocellular carcinomas are *de novo* cases that usually are not related to hepatic cirrhosis or other preexisting liver disease. This is in contrast to hepatocellular carcinoma in adults, in whom 70% to 90% of cases are related to cirrhosis.⁴³⁻⁴⁶

Despite differences in etiology, the macroscopic and microscopic features of hepatocellular carcinoma in children and adults are similar.⁴⁷ The classic trabecular pattern and fibrolamellar variants are the two most common types of hepatocellular carcinoma in children. It has been observed that there are improved outcomes associated with the fibrolamellar subtype in adults, but this has not been reported in the pediatric population.^{24,48-50}

Hepatocellular carcinoma frequently is manifested with abdominal fullness associated with pain or discomfort. Other common signs and symptoms include weight loss and fatigue. The most common clinical finding on physical examination is hepatomegaly. At presentation, between 60% and 80% of children with hepatocellular carcinoma have elevated serum α -fetoprotein levels. Metastatic disease at the time of presentation is common, and typical sites of metastasis include regional lymph nodes, lungs, and bone. Therapeutic results are uniformly poor, with an overall survival rate of about 20%.^{47,51-54} Complete tumor excision remains the only chance for long-term survival. Because of a high rate of metastatic disease at presentation (up to 50% of children) and because hepatocellular carcinoma in children is often multifocal, complete tumor excision is possible in only a minority of cases.^{26,39,51} The question of optimal therapy for pediatric hepatocellular carcinoma remains controversial, and the role of liver transplantation remains a matter for debate.

The imaging findings for hepatocellular carcinoma in children do not differ significantly from those seen in adults and are nonspecific, with variable appearance of the tumors on ultrasound, CT, and MRI. On ultrasound, hepatocellular carcinoma is typically hypoechoic to isoechoic compared with normal hepatic parenchyma. When the tumor is infiltrative, there may be subtle disruption of the normal liver echotexture.⁵⁵ CT can demonstrate a solitary mass, infiltrative tumor, or multiple, confluent masses that are low attenuating to isoattenuating relative to normal hepatic parenchyma on noncontrast or portal venous phase studies. With contrast-enhanced CT, these tumors may be hyperattenuating (Fig. 120-6). Calcifications are uncommon, but hemorrhage and necrosis are frequently seen. With T1-weighted MRI, hepatocellular carcinoma is frequently hypointense to normal hepatic parenchyma, but tumors may also appear isointense to hyperintense. Lesions of mixed signal intensity are seen in the setting of hemorrhage, necrosis, or fatty metaplasia. On T2-weighted images, most lesions demonstrate moderately increased signal intensity.

Undifferentiated Embryonal Sarcoma

Undifferentiated embryonal sarcoma is a rare, highly malignant hepatic neoplasm of mesenchymal origin that occurs almost exclusively in the pediatric population. It is the third most common primary hepatic malignant neoplasm of childhood. The age distribution for undifferentiated embryonal sarcoma

Figure 120-6 Hepatocellular carcinoma. Arterial phase (A) and portal venous phase (B) dynamic CT through the upper abdomen in a 12-year-old girl who presented with an abdominal mass demonstrates a large, heterogeneous mass with early enhancement on the arterial phase CT scan. The child had no underlying liver disease.

falls between the peak ages of the incidence for hepatoblastoma and hepatocellular carcinoma, in children between the ages of 6 and 10 years, with no gender predilection.¹⁷ On histologic examination, this tumor consists of undifferentiated spindle cells that resemble embryonal cells with a myxoid stroma. The tumor typically is well demarcated by a fibrous pseudocapsule.⁵⁶

Undifferentiated embryonal sarcoma usually is manifested as a large abdominal mass, although pain, fever, jaundice, and weight loss have been reported.²⁵ On occasion, children with this tumor present with an acute abdomen after the tumor ruptures. There are no reliable serum markers for this tumor, although leukocytosis and anemia may be present. Serum α -fetoprotein levels are normal.⁵⁷

Undifferentiated embryonal sarcoma varies in sonographic appearance from a septate, cystic mass to a heterogeneous, predominantly solid lesion. The solid lesions may demonstrate high-level echoes with acoustic shadowing from calcifications. On noncontrast CT, undifferentiated embryonal sarcoma is frequently hypoattenuating. There may be enhancement of the internal septa and fibrous capsule after administration of contrast material.⁵⁸ On MRI, undifferentiated embryonal sarcomas typically appear heterogeneous; these tumors usually are hypointense on T1-weighted sequences and hyperintense on T2-weighted sequences, corresponding to the cystic components of the mass. The fibrous pseudocapsule and internal septations appear hypointense on T1-weighted and T2-weighted sequences (Fig. 120-7).⁵⁹

Hepatic Angiosarcoma

Hepatic angiosarcoma is a rare, high-grade malignant neoplasm of endothelial cells.⁶⁰⁻⁶⁴ Unlike hepatic angiosarcoma in the adult population, pediatric hepatic angiosarcoma affects girls more than boys, with a female-to-male ratio of approximately 2:1. There is a lack of clear association with environmental carcinogens such as arsenic and polyvinyl chloride.⁶⁵ The mean age at presentation is 40 months. Pediatric hepatic angiosarcoma usually is manifested as an abdominal mass that may be associated with jaundice, abdominal pain, vomiting, fever, tachypnea, dyspnea, or anemia (Fig. 120-8). Consumption coagulopathy, which frequently occurs in adults with hepatic angiosarcoma, has not been described in children.

Pediatric hepatic angiosarcoma differs histologically from adult hepatic angiosarcoma. Pediatric hepatic angiosarcoma

can have hypercellular whorls of sarcomatous cells or kaposiform spindle cells similar to kaposiform hemangioendothelioma of soft tissue in addition to the features of adult angiosarcoma.⁶⁶ This tumor typically is manifested as a rapidly enlarging abdominal mass, and it usually is unresectable at presentation. Metastatic disease, particularly to the lungs, is a common early occurrence.^{61,62,67} Pediatric hepatic angiosarcoma has been described in the background of infantile hemangioendothelioma, and it therefore may be missed on the initial biopsy specimen.^{61,62,67,68} Because of the possibility of an association between infantile hemangioendothelioma and pediatric hepatic angiosarcoma, a presumptive diagnosis of infantile hemangioendothelioma in a child older than 1 year should probably be followed by a biopsy. There are no clear radiographic features to distinguish the two tumors.⁶⁷

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma is a very rare malignant neoplasm of vascular origin arising in soft tissues, lung, and liver that has malignant potential intermediate between infantile hemangioendothelioma and hepatic angiosarcoma.^{69,70} On histopathologic examination, the tumor consists of epithelioid and dendritic cells. The center of the tumor is predominantly

Figure 120-7 Undifferentiated embryonal sarcoma. Axial T1-weighted MRI through the upper abdomen in an 8-year-old girl demonstrates a bilobed mass arising from the left hepatic lobe.

Figure 120-8 Hepatosarcoma. Dynamic, contrast-enhanced CT image reveals a large, low-density liver mass arising in the right lobe and extending into the medial segment of the left lobe. **A.** Arterial phase. **B.** Delayed scan.

fibrous stroma. This tumor may infiltrate the hepatic sinusoids and portal branches and, in doing so, obliterate them. These features may be misinterpreted as veno-occlusive disease.⁷¹ Splenomegaly, ascites, and portal hypertension may be present. Epithelioid hemangioendothelioma typically occurs after the second decade of life and is manifested with various clinical symptoms.

Epithelioid hemangioendotheliomas tend to be multifocal or multicentric at presentation. Metastatic disease is seen at presentation in approximately 27% to 45% of patients.^{71,72} Ultrasound characteristics of this tumor vary and are nonspecific. Tumors have been described as hypoechoic, isoechoic, and hyperechoic.⁷² Internal calcifications may be present. The lesions are hypoattenuating relative to normal hepatic parenchyma on unenhanced CT. After intravenous administration of contrast material, there is typically peripheral enhancement followed by relatively uniform enhancement that is isoattenuating compared with hepatic parenchyma. MRI may depict tumor characteristics better than CT.⁷³ On T1-weighted sequences, the tumor typically demonstrates decreased signal relative to normal hepatic parenchyma and demonstrates peripheral enhancement after intravenous administration of gadolinium. The lesions may be relatively heterogeneous on T2-weighted sequences.⁷³

Epithelioid hemangioendothelioma tumors are notable for resistance to chemotherapy and radiation therapy. The primary treatment of choice is radical hepatic resection or liver transplantation.

SECONDARY MALIGNANT NEOPLASMS

The most commonly encountered secondary or metastatic hepatic malignant neoplasms in children include neuroblastoma, Wilms' tumor, lymphoma, and leukemia. Metastatic disease typically appears as solitary or multiple discrete masses within the hepatic parenchyma, although leukemia may be manifested with a diffuse infiltrative pattern.^{16,17} Stage IVS neuroblastoma, in which infants have metastases confined to the liver, skin, or bone marrow, usually is manifested as diffuse infiltration of the hepatic parenchyma. Hepatic metastases usually appear hypoechoic on ultrasound, but diffuse involvement of the liver may be difficult to detect. On CT, metastatic disease typically appears as hypoattenuating lesions, although care should be taken during portal venous phase scanning

because some metastases become isoattenuating during this phase (Figs. 120-9 and 120-10). Metastatic disease in the liver typically has low signal intensity on T1-weighted MR sequences and high signal intensity on T2-weighted sequences.

Benign Hepatic Neoplasms and Neoplasm-Like Abnormalities

PEDIATRIC HEPATIC VASCULAR LESIONS

Vascular lesions of the pediatric liver can be divided into two main categories by their biologic characteristics.⁷⁴ Hepatic vasoproliferative tumors include infantile hemangioendothelioma, angiosarcoma, and epithelioid hemangioendothelioma. Vascular malformations include arteriovenous malformations, arterioportal fistula, and portosystemic shunts.

Infantile Hemangioendothelioma

Infantile hemangioendothelioma is a benign but frequently symptomatic vascular neoplasm. These lesions are the most

Figure 120-9 Burkitt's lymphoma. Contrast-enhanced CT of the upper abdomen reveals multiple, low-attenuation liver masses from metastatic Burkitt's lymphoma in a 6-year-old boy. Notice the multiple, low-attenuation renal lesions, which also result from metastatic Burkitt's lymphoma.

Figure 120-10 Liver metastases from neuroblastoma. A 12-month-old child with a primary pelvic neuroblastoma was found to have multiple liver metastases. The focal lesions are best seen on precontrast scans (A), and they become almost isodense after administration of contrast material (B).

common hepatic masses in infancy, and most are manifested within the first 2 to 6 months of life.^{75,76} Only 5% of infantile hemangioendotheliomas are detected in children older than 1 year. Girls are more frequently affected than boys, with a ratio of between 1.3 and 2 girls to 1 boy. Infantile hepatic hemangioendothelioma is a proliferative, predominantly endothelial cell hepatic neoplasm, with characteristic periods of rapid growth due to cellular proliferation followed by spontaneous involution. It is important to differentiate infantile hemangioendothelioma from epithelioid hemangioendothelioma and adult hepatic hemangioma. Epithelioid hemangioendothelioma is a proliferative neoplasm with malignant potential that does not involute over time, and adult hepatic hemangioma represents a vascular malformation that does not spontaneously regress.

Infantile hemangioendotheliomas typically are manifested in young infants as hepatomegaly. In 10%, there is associated high-output congestive heart failure due to vascular shunting. Failure to thrive, anemia, thrombocytopenia, and respiratory distress are other commonly associated symptoms. Anemia and thrombocytopenia may be related to consumptive coagulopathy (Kasabach-Merritt syndrome). Tumor rupture with intraperitoneal hemorrhage has also been described.^{77,78} Cutaneous hemangiomas and hemangiomas of other organs are seen in approximately 50% of children with these tumors.

Ultrasound, CT, and MRI are able to define the classic secondary features of these high-flow lesions, including tapering of the abdominal aorta below the level of the superior mesenteric artery and prominent feeding vessels. Typically, these lesions are well-circumscribed, hypoechoic lesions on ultrasound, although the solitary or focal lesions may be more heterogeneous (Fig. 120-11).⁵⁵ On noncontrast CT, most hemangioendotheliomas appear hypoattenuating compared with normal hepatic parenchyma. Finely stippled calcifications may be observed. After injection of contrast material, there is centripetal enhancement of the lesion, with the periphery of a lesion enhancing first (Fig. 120-12). Delayed scans generally demonstrate uniformly hyperattenuating masses or mass. Large focal lesions may appear heterogeneous with varying enhancement patterns, including lack of enhancement in the central portion because of fibrosis (Fig. 120-13).⁷⁹ The MR appearance of hemangioendotheliomas depends on the degree of tumoral necrosis or hemorrhage. Classically, infantile

hemangioendothelioma appears as a well-defined, spherical lesion with signal characteristics that are hypointense relative to liver on T1-weighted sequences and vividly hyperintense on T2-weighted sequences. Intratumoral flow voids related to increased vascular shunting may be present.

Initial management of an infant with a hepatic hemangioendothelioma should be conservative because most lesions spontaneously involute without therapy during several months to years.¹⁶ These lesions are often observed with sequential ultrasound examinations until they involute. Therapeutic

Figure 120-11 Hemangioendothelioma. Ultrasound of the liver in the sagittal plane in a 1-month-old girl with hepatomegaly demonstrates multiple, hypoechoic masses throughout the hepatic parenchyma due to multicentric hemangioendothelioma.

Figure 120-12 Multifocal hemangioendothelioma of the liver in a 2-week-old girl who presented with hepatomegaly. **A.** Noncontrast CT of the abdomen demonstrates multiple, low-attenuation lesions within both lobes of the liver. **B.** After the intravenous administration of contrast material, there is dense peripheral enhancement of these lesions.

Figure 120-13 Hemangioendothelioma in a newborn. This newborn had congestive heart failure, thrombocytopenia, and hepatomegaly. **A.** Noncontrast CT reveals an irregular mass in the right lobe containing small, punctate calcifications. **B.** After the bolus administration of contrast material, there is dense, peripheral enhancement of the mass, which has frondlike extensions into the surrounding liver parenchyma. Notice the large caliber of the aorta. **C.** On delayed scans, there is partial enhancement of the peripheral margins of the mass.

Figure 120-14 Hepatic arteriovenous malformation. **A.** Ultrasound of the posterior right hepatic lobe in an infant reveals a large arteriovenous malformation with direct communication between the right hepatic vein and the hepatic artery (arrow). **B.** On the axial contrast-enhanced CT scan of the liver in the same infant with a large arteriovenous malformation involving the posterior right hepatic lobe, notice the lack of hepatic parenchyma between the abnormal vessels.

options include steroids, interferon alfa-2a, embolization, and, less frequently, chemotherapy, radiotherapy, surgery, or liver transplantation in refractory cases.

Arteriovenous Malformations

Hepatic arteriovenous malformations (AVMs) are congenital abnormalities of blood vessels that result in shunting of blood through direct communications between the arterial and venous systems. These anomalies contain no abnormal tissue between the anomalous vessels and lack potential for growth or regeneration. In the neonatal period, hepatic AVMs are manifested with congestive heart failure, anemia, hepatomegaly, and portal hypertension. In infants, AVMs are usually solitary, and imaging findings may show considerable overlap with those seen in the

setting of a solitary hepatic hemangioma (see Fig. 120-15). Patients with hereditary hemorrhagic telangiectasia may present in late childhood with symptoms of congestive heart failure, hepatic ischemia, and portal hypertension. Unlike with the AVMs typically encountered during infancy, children with hereditary hemorrhagic telangiectasia typically have diffuse disease.

Hepatic AVMs may appear sonographically as a cluster of enlarged, tortuous vessels confined to one lobe of the liver, with increased venous pulsatility and decreased arterial resistive indices (Fig. 120-14). These lesions demonstrate intense homogeneous enhancement on CT with the intravenous administration of contrast material during the arterial or early portal venous phase, followed by rapid clearing of the contrast

material. MRI is particularly useful for differentiating hepatic AVMs from hepatic hemangiomas.⁸⁰ On contrast-enhanced MRI, AVMs lack the delayed contrast enhancement around the tortuous vessels that is commonly seen with hemangiomas.⁸¹

Arterioportal Fistula

Most hepatic arterioportal fistulas are isolated congenital anomalies, although these vascular lesions may be acquired and can be seen in the setting of hereditary hemorrhagic telangiectasia or Ehlers-Danlos syndrome.⁸² In infants and young children, a hepatic arterioportal fistula most commonly is manifested as portal hypertension with ascites, malabsorption, and gastrointestinal bleeding, although high-output cardiac failure has also been described.⁸² The lesion has a variable appearance, but it typically contains a large intrahepatic varix with a single arteriovenous connection that distinguishes it from an AVM, which contains multiple feeding vessels.⁸³ This lesion may be differentiated from focal hemangioma in infants by the lack of enhancing tissue around the varix. Treatment may consist of lobectomy if embolization is unsuccessful.⁸⁴

Portosystemic Shunts

Congenital portosystemic shunts, although rare, are a recognized cause of hyperammonemia and galactosemia in infants and children.⁸⁵⁻⁸⁷ Intrahepatic and extrahepatic portosystemic shunts have been described.^{80,85-89} Prognostic factors are related to the type of shunt, shunt ratio, and age of the patient. Most intrahepatic portosystemic shunts spontaneously close within the first 2 years of life, and asymptomatic children with this anomaly may be observed with serial ultrasound examinations.^{80,85}

Congenital intrahepatic portosystemic shunts are anomalous communications between branches of the portal vein and hepatic veins that are thought to be the sequelae of absent venous sinusoids.⁸⁸ Ultrasound of the liver typically shows communication of the hepatic and portal vein branches through tubular, anechoic structures. Doppler evaluation may be useful for documentation of the vascular communication and evaluation of the shunt ratio. The presence of a portosystemic shunt should be suspected when a pulsatile biphasic or triphasic spectral pattern is encountered in the portal vein or its branches.

Extrahepatic portosystemic shunts include congenital absence of the portal vein and a side-to-side communication

between the portal vein and the inferior vena cava. These anomalies have a high association with other congenital malformations, such as complex congenital heart disease, heterotaxy syndromes, Goldenhar's syndrome, and biliary atresia, but they have also been described in asymptomatic children undergoing imaging for other reasons.⁸⁰ Absence of the portal vein may be detected with ultrasound by the presence of only the hepatic artery and common bile duct at the hepatic hilum. Cross-sectional imaging with CT or MRI provides better delineation of the course of the extrahepatic portosystemic shunt, particularly when postprocessing volume-rendering techniques are used.

MESENCHYMAL HAMARTOMA

Mesenchymal hamartoma of the liver is a rare, benign, predominantly cystic mass of infancy and young childhood; most patients present before the age of 2 years. This lesion is considered to be a developmental anomaly rather than a true neoplasm of the liver, and it is composed of bile ducts, hepatocytes, mesenchymal tissue, and vessels. The tumor is commonly predominantly cystic, but tumors with a large solid component occasionally occur.⁹⁰ The tumor is often large at presentation, frequently weighing more than 1000 g, and it commonly occupies the right hepatic lobe, although both lobes may be involved. Patients typically present with a large, asymptomatic abdominal mass and have normal serum α -fetoprotein levels.

Ultrasound can characterize these lesions well by delineating the cystic and septate nature of the mass and any solid components, but contrast-enhanced CT better delineates the relationship of the mass to adjacent structures. There should be little enhancement of the septa after intravenous administration of contrast material, but when a soft tissue component is present, enhancement may be inhomogeneous (Fig. 120-15). On MRI, the cystic component demonstrates inconsistent signal patterns that correspond to the variable content of proteinaceous fluid.⁹¹

Although mesenchymal hamartoma is a benign lesion and can often be differentiated from other liver tumors radiographically with a high degree of confidence, surgical resection remains the mainstay of treatment. Resection is generally curative, although enucleation followed by incision and drainage

Figure 120-15 Mesenchymal hamartoma. **A.** Contrast-enhanced axial CT through the upper abdomen in an infant demonstrates a large cystic liver mass occupying both lobes. Notice the enhancement of the single septation. **B.** Axial T1-weighted MRI demonstrates the same lesion, which is almost entirely cystic.

of the cystic components and nonoperative management with serial imaging have been reported.^{92,93} Transplantation remains an option in children for whom surgical resection is not possible.⁹⁴

HEPATIC ADENOMA

Hepatic adenomas are unusual tumors in the general pediatric population, but they may be encountered more frequently in children with predisposing systemic diseases or in teenage girls, particularly those taking oral contraceptive pills. Children with Fanconi anemia who are treated with exogenous steroids and patients with type 1 glycogen storage disease are at increased risk for adenomas and other hepatic neoplasms.⁹⁵⁻⁹⁷ In children with type 1 glycogen storage disease, hepatic adenomas are more likely to be multiple (Fig. 120-16).⁹⁸

Adenomas are typically solitary lesions associated with normal serum α -fetoprotein levels. They may be found incidentally, but they are prone to acute hemorrhage, causing sudden

onset of abdominal pain (Fig. 120-17). Because of the complications related to sudden hemorrhage, these lesions are treated with surgical resection.

FOCAL NODULAR HYPERPLASIA

Focal nodular hyperplasia is the second most common benign, solid hepatic neoplasm in adults after hemangioma, but it is rare in the pediatric population (Fig. 120-18). Historically, focal nodular hyperplasia was considered a hamartoma or neoplasm related to ischemic changes, but this benign tumor is now considered to be a non-neoplastic, hyperplastic response to a congenital or acquired vascular malformation.³ It is postulated that focal circulatory disturbances cause arterial and portal venous thrombosis. Vascular recanalization and reperfusion of hepatic tissue may lead to hepatocyte proliferation and the development of focal nodular hyperplasia^{3,99} and other non-neoplastic lesions, such as regenerative nodules.¹⁰⁰

LYMPHOPROLIFERATIVE DISORDERS

Lymphoproliferative disorder is becoming more common in the pediatric population as the number of immunocompromised children grows. Solid organ and stem cell transplantation are being used more widely in children, and there is increased survival of children with immunologic disorders. Lymphoproliferative disorder results from T-cell dysfunction and abnormal proliferation of B cells infected with Epstein-Barr virus. This disorder encompasses a wide spectrum of disease, from polyclonal B-cell hyperplasia to monoclonal B-cell lymphoma.^{101,102} Lymphoproliferative disorder is most commonly seen after solid organ transplantation, but it also occurs in children after stem cell transplantation.

After solid organ transplantation, lymphoproliferative disorder commonly occurs in the region of the allograft, with hepatic involvement most frequently occurring after liver transplantation.¹⁰² Hepatic disease may be manifested as regions of periportal low attenuation or discrete masses.^{102,103} Hepatic masses related to lymphoproliferative disorder may be distinguished from other causes of liver masses by their tendency to invade and encase the portal veins rather than displace them.¹⁸

Figure 120-16 Adenoma. Contrast-enhanced CT through the liver of a child with Gaucher's disease reveals an enhancing, well-circumscribed mass arising from the lateral aspect of the left hepatic lobe. At surgical resection, this lesion proved to be an adenoma. Notice the hepatomegaly and decreased attenuation of the liver due to Gaucher's disease.

Figure 120-17 Adenoma with hemorrhage. A and B. Axial CT images after intravenous contrast enhancement in an 11-year-old girl who experienced acute onset of abdominal pain after karate class. The large, hemorrhagic tumor occupying the right hepatic lobe was found to be an adenoma at resection.

Figure 120-18 Focal nodular hyperplasia. The newborn was found to have an enlarged liver on physical examination. CT images reveal a round mass in the inferior aspect of the right lobe that has the same density as surrounding parenchyma before (A) and after (B) contrast enhancement. MRI reveals a signal intensity equal to that of surrounding parenchyma on T1-weighted (600/30) (C) and T2-weighted (2000/80) (D) sequences.

Focal Inflammatory-Infectious Lesions of the Liver

Focal hepatic infections are described in detail in Chapter 88. This section focuses on the aspects of hepatic inflammatory lesions specific to children. Hepatic abscesses are often caused by bacterial, fungal, or granulomatous infections. Amebic abscesses and hydatid cysts are common worldwide but occur infrequently in the general pediatric population in developed countries.

Pyogenic bacterial hepatic abscesses require prompt diagnosis and treatment because they may be life-threatening. In infants, hepatic abscesses are associated with generalized sepsis or may be a sequela of umbilical line placement. In older children, sepsis is a common cause, although pyogenic liver abscesses may also be seen after trauma or in immunocompromised patients such as children with sickle cell anemia or an immunologic deficiency (Fig. 120-19). On occasion, pyogenic hepatic abscesses can result from perforated appendicitis (Fig. 120-20). In children who have undergone stem cell transplantation or who are immunocompromised as the result of chemotherapy, hepatic and splenic abscesses related to disseminated fungal infection are more common.¹⁸ The most frequent causative organisms in these patients are *Candida albicans* and *Aspergillus* species. Cat-scratch disease is a benign, self-limited systemic infection associated with regional lymphadenopathy that commonly affects the liver. Hepatic involvement typically is manifested as multiple, small, nodular lesions. This infection, caused by *Bartonella henselae*, typically follows a cat scratch or multiple skin abrasions.

Figure 120-19 Chronic granulomatous disease. A low-attenuation hepatic abscess is seen in the dome of the right hepatic lobe in a teenage boy. Percutaneous drainage is unrewarding because there is little purulent material and mostly granuloma.

Chronic granulomatous disease is an inherited immune deficiency that results in an abnormality of leukocytes. This disorder is most commonly inherited in an X-linked fashion and therefore occurs most commonly in boys. Chronic granulomatous disease is characterized by a combination of several molecular defects that result in defective NADPH oxidase activity in

Figure 120-20 Pyogenic liver abscess. **A.** Multiple, mixed-attenuation lesions are seen in the liver of this 15-year-old girl with perforated appendicitis. **B.** Notice the thrombus in the superior mesenteric vein (arrow) in the same child.

Figure 120-21 Chronic granulomatous disease. Multiple hepatic lesions are found on the CT scan of a 9-year-old boy. CT demonstrates calcifications from prior infections and low-attenuation masses from an active infection.

leukocytes.¹⁰⁴ Children with chronic granulomatous disease develop recurrent infections, commonly with catalase-positive bacteria such as *Staphylococcus aureus* or fungi, including *Aspergillus*, because of defective intracellular killing by neutrophils (Fig. 120-21).¹⁰⁵ This disease usually is manifested in children younger than 1 year with pulmonary infections. Other sites of involvement include the lymph nodes, skin, liver, gastrointestinal tract, and bones.¹⁰⁶

Neonatal Jaundice

Unconjugated hyperbilirubinemia is a common physiologic event in normal newborns, occurring in approximately 60% of term infants and 80% of preterm infants. Hyperbilirubinemia generally peaks in days 5 to 7 of life, with bilirubin levels typically below 12 to 14 mg/dL.¹⁰⁷ Infants who are breast-fed may have prolonged elevation of bilirubin through the second week of life. Onset of neonatal jaundice within the first 24 hours of life, rapid rise of serum bilirubin levels (>5 mg/dL in 24 hours), persistent jaundice, new onset of jaundice after 2 weeks of life, or a direct bilirubin level above 1 mg/dL should increase

suspicion that the neonatal jaundice may be pathologic.^{108,109} In these children, further evaluation is needed for infectious, metabolic, or surgical causes of jaundice. During the neonatal period, neonatal hepatitis, biliary atresia, and choledochal malformation/cyst are the three most common causes of jaundice.¹¹⁰ Biliary atresia and choledochal cysts are discussed in detail in Chapter 119.

Neonatal hepatitis is more common in male infants than in female infants and typically occurs during the first month of life. The spectrum of diseases associated with neonatal hepatitis includes hepatitis A, hepatitis B, hepatitis C, protozoan infections, toxoplasmosis, syphilis, rubella, cytomegalovirus infection, herpesvirus infection, inborn errors of metabolism, familial cholestasis, and idiopathic causes.¹⁰⁸⁻¹¹⁰

Ultrasound is the initial imaging tool in neonates with jaundice and is particularly useful in the differentiation of a choledochal cyst or dilation of the bile ducts from other causes of obstruction. In infants with neonatal hepatitis, the sonographic appearance of the liver may be normal to enlarged, with variable increased or decreased echogenicity. The biliary ducts and gallbladder are typically normal, except in cases with severe hepatocellular dysfunction. In these infants, decreased bile production may cause the gallbladder to appear small.¹¹⁰ In neonates with poor bile excretion due to hepatic dysfunction, sonographic differentiation of neonatal hepatitis from biliary atresia can be challenging. In these children, nuclear medicine hepatobiliary scintigraphy should be performed to assess for excretion of bile into the small intestine.

Cirrhosis and Diffuse Disorders of the Liver

Cirrhosis is a diffuse disease of the liver that results from destruction of normal hepatic parenchyma and the development of fibrosis. Regeneration of liver parenchyma occurs in a focal nodular pattern that may be micronodular or macronodular. Portal hypertension is commonly seen in the setting of cirrhosis. Cirrhosis in children usually occurs as the sequela of congenital or acquired disease of the liver, including biliary atresia, hepatitis, congenital hepatic fibrosis, cystic fibrosis, Budd-Chiari syndrome, and chronic biliary obstruction. Cirrhosis is also a secondary phenomenon in a variety of metabolic disorders, including α_1 -antitrypsin deficiency, Wilson's

Figure 120-22 Tyrosinemia. The liver has irregular contours, multiple low-attenuation lesions within the parenchyma, and patchy enhancement in a patient with tyrosinemia. The child underwent transplantation.

disease, glycogen storage disease, tyrosinemia, and galactosemia (Fig. 120-22).

α_1 -ANTITRYPSIN DEFICIENCY

The most common genetic cause of severe liver disease in children is α_1 -antitrypsin deficiency. A relative deficiency of an antiproteolytic enzyme results in accumulation of hepatic toxins, which leads to the destruction of hepatic architecture and cirrhosis, with the associated imaging findings. Individuals are also at risk for clinical manifestations such as emphysema, panniculitis, and perhaps even granulomatosis with polyangiitis (formerly Wegener's granulomatosis).¹¹¹⁻¹¹³

CYSTIC FIBROSIS

The frequency and severity of hepatobiliary complications in children with cystic fibrosis have increased with the improved life expectancy of those with this disorder.¹¹⁴ Cystic fibrosis-related hepatobiliary disease includes chronic cholangitis, fibrosis, fatty changes, and focal biliary cirrhosis that may progress to profound hepatic cirrhosis with portal hypertension, abnormalities of the bile ducts, and gallbladder abnormalities, including cholelithiasis.¹¹⁵

GLYCOGEN STORAGE DISEASES

The glycogen storage diseases are a group of inherited metabolic disorders, most of which have an abnormality in the breakdown of glycogen to glucose, which is manifested as

Figure 120-23 Gaucher's disease. CT scan through the liver of a 9-year-old boy reveals a distorted hepatic contour, peripheral parenchymal enhancement, and central region of relatively low density surrounding the portal branches. The patient died within a few days of this CT study. At autopsy, the central portion of the liver was replaced with fibrosis.

abnormal structure or concentration of glycogen. The six types are classified by differences in a specific enzyme defect. Type 1 (von Gierke's disease) is distinguished by a defect in the breakdown of glycogen to glucose, resulting in excess accumulation of glycogen within hepatocytes and the proximal convoluted tubules of the kidneys. Children with type 1 glycogen storage disease have an increased incidence of hepatic adenomas and hepatocellular carcinomas. Hepatomegaly, splenomegaly, and cirrhosis are characteristic in several different types of glycogen storage disease.

GAUCHER'S DISEASE

Gaucher's disease is a rare genetic disorder of glycolipid metabolism that leads to abnormal accumulation of glucocerebroside in cells of the reticuloendothelial system. Hepatomegaly may be the only imaging abnormality seen in the liver, but some children exhibit focal areas of low-intensity T1-weighted and high-intensity T2-weighted signal on MRI, patterns that are presumably related to deposition of Gaucher cells and fibrosis. Portal hypertension in these children is uncommon. Liver and spleen volumes determined by ultrasound, CT, or MRI are useful as an indicator of disease progression and may correlate with changes in the bone marrow and the development of avascular necrosis (Fig. 120-23).¹¹⁶⁻¹¹⁹

Diseases of the Pediatric Pancreas

MARIAM M. KAPPIL | DARSHIT J. THAKRAR

CHAPTER OUTLINE

Imaging of the Pediatric Pancreas

Trauma

Pancreatitis

Acute Pancreatitis

Chronic Pancreatitis

Cystic Fibrosis

Shwachman-Diamond Syndrome

Nesidioblastosis

Pancreatic Masses

Congenital Cysts

Neoplasms

Metastatic Disease

Miscellaneous Processes

von Hippel–Lindau Disease

Beckwith–Wiedemann Syndrome

Autosomal Dominant Polycystic Kidney Disease

Imaging of the Pediatric Pancreas

Ultrasound is the initial imaging modality of choice for evaluation of the pediatric pancreas. The relatively large left hepatic lobe serves as an acoustic window and children have a thin body habitus, which makes this possible.¹ Ultrasound is also ideal for imaging of children because it is noninvasive and does not require sedation, along with the lack of ionizing radiation.² On sonography, the normal pancreas has a homogeneous echotexture (Fig. 121-1).³ The pancreas in preterm infants and neonates usually is more echogenic than the liver.⁴ As children grow, it usually becomes nearly isoechoic to the liver. The normal pancreatic duct is commonly seen in the body of the gland as an echogenic line or an anechoic lumen with echogenic borders (Fig. 121-2).^{1,3} Relative to body size, the pancreas is larger in children than in adults, although it tends to shrink relatively with age.^{2,5} The head and tail of the pancreas typically are thicker than the body and neck. The usual prominence of the head can sometimes be mistaken for abnormality. The pancreatic duct normally is less than 2 mm in diameter.⁶

Given the ionizing radiation, the need for intravenous and oral administration of contrast material, and the possible need for sedation of young patients, computed tomography (CT) is usually reserved for when the ultrasound study is nondiagnostic. It is also used to more clearly define anatomic detail (such as pancreatic mass, severe pancreatitis, or the complete extent of disease), to evaluate blunt abdominal trauma,¹ and to assess the distant complications of pancreatic disease. On CT, the normal pediatric pancreas has a generally smooth or slightly

lobulated surface and a homogeneous soft tissue attenuation² that is usually similar to that of the liver (Fig. 121-3).⁵

Magnetic resonance imaging (MRI), when it is coupled with magnetic resonance cholangiopancreatography (MRCP), is a powerful, noninvasive tool for imaging of the pancreatic and biliary ductal systems.² On fat-saturated T1-weighted images, the pancreas demonstrates intrinsic T1 hyperintensity and is of bright signal compared with other organs. On T2-weighted images, the pancreas should be isointense to the liver.⁷ MRCP is useful to evaluate the ductal anatomy in children with acute or recurrent pancreatitis for congenital abnormalities, such as pancreas divisum or an abnormal pancreatobiliary junction.⁸ The disadvantages of MRI include its expense, technical difficulty (particularly in younger children, who are unable to cooperate), and poor spatial resolution with regard to peripheral pancreatic and biliary anatomy.⁸

Whereas endoscopic retrograde cholangiopancreatography (ERCP) has been the “gold standard” for evaluating the pancreatic and biliary ductal systems, its utility has decreased with the advent of MRCP. This technique has the disadvantages of being invasive, requiring general anesthesia in children, and having the potential complication of pancreatitis, which occurs in at least 3% of children.¹ Thus, ERCP is now usually reserved for cases that require intervention or for manometry of biliary and pancreatic sphincters.⁹

Trauma

Blunt abdominal trauma accounts for most abdominal injuries in children.¹⁰ Children are more prone to trauma-induced pancreatic injury than adults are because of underdeveloped abdominal musculature.² The mechanism of injury most commonly involves compression of the pancreas against the spine, as seen in motor vehicle collisions or nonaccidental trauma, or discrete focal trauma,¹⁰ commonly seen in bicycle handlebar injuries.⁵ There is overall approximately 3% to 12% incidence of pancreatic injury in children,¹⁰ with 90% of these patients also concurrently having injuries to other structures, including the liver, spleen, bowel, and adjacent vasculature.¹¹ The bicycle handlebar type is the most likely to cause isolated injury to the pancreas (Fig. 121-4).¹²

The signs and symptoms of pancreatic injury may be delayed for hours or days after the trauma, particularly if the injury is isolated to the pancreas.¹⁰ Symptoms are often atypical and nonspecific, including abdominal pain, nausea, vomiting, and fever.² The initial serum amylase level has a low sensitivity and specificity for detecting pancreatic injury, and it may be normal, even in the setting of significant pancreatic injury.¹²

The utility of ultrasound is limited in the setting of blunt abdominal trauma, with a sensitivity of only 67% for detecting pancreatic injury seen by CT.¹² Contrast-enhanced CT is superior to ultrasound for evaluating pancreatic trauma, with a sensitivity for detecting all pancreatic injuries of 85% within 24

Figure 121-1 Normal pancreas. The transverse ultrasound image of the pancreas demonstrates pancreatic echogenicity similar to that of the adjacent liver.

Figure 121-2 Normal pancreatic duct. The transverse sonographic image of the pancreas demonstrates parallel echogenic lines in the body of the pancreas consistent with a normal pancreatic duct (arrows).

hours of admission.¹² Admission CT findings may be normal in patients later proved to have pancreatic injury by repeated imaging or laparotomy.¹⁰ Early findings of pancreatic injury can be subtle, especially immediately after trauma.² Unlike other traumatized abdominal solid organs, the pancreas can have little change in attenuation with lacerations and fractures, making diagnosis difficult, particularly if there is no separation of the parenchymal fragments (Fig. 121-5).^{2,13}

Figure 121-3 Normal pancreas. The contrast-enhanced CT scan demonstrates a normal pancreas with a gently lobulated surface in a 7-year-old girl. The attenuation of the pancreas is similar to that of the adjacent liver.

Figure 121-4 Pancreatic contusion. The CT scan through the pancreas reveals focal low attenuation in the body of the pancreas caused by contusion (arrows) in a young boy after abdominal trauma from a bicycle handlebar.

Pancreatic contusions or lacerations tend to occur at the junction of the body and tail of the pancreas.¹⁴ They are manifested as linear areas of low attenuation perpendicular to the long axis of the pancreas (Fig. 121-6),^{1,2,5} and there may be associated pancreatic edema and enlargement, pancreatic or duodenal hematoma, and pancreatic duct dilation.^{2,12} Peripancreatic fluid or fluid in the lesser sac is a useful marker for pancreatic injury, particularly in the absence of injury to other organs.¹ The failure to visualize a portion of the gland should suggest the diagnosis of pancreatic

Figure 121-5 Pancreatic contusion. **A.** The CT scan through the upper abdomen of a young girl involved in a motor vehicle accident is limited by significant motion artifact. **B.** The repeated scan through the upper abdomen shows heterogeneous low attenuation in an enlarged pancreas that represents pancreatic contusion and edema (arrows). The patient also has moderate free intraperitoneal fluid.

Figure 121-6 Pancreatic contusion. The CT scan through the upper abdomen of a 3-year-old boy after a motor vehicle accident shows focal low attenuation in the pancreatic head in the typical distribution anterior to the spine (small arrow). The patient also has free intraperitoneal air from a duodenal laceration (large arrow).

Figure 121-7 Pancreatic transection. The CT scan through the pancreas in a young child after nonaccidental trauma demonstrates complete pancreatic transection (arrow).

laceration.¹⁴ Complete pancreatic transection is rare (Fig. 121-7).¹⁴ Blunt trauma is the most common cause of acute pancreatitis in children.⁵ In the setting of post-traumatic acute pancreatitis in children, CT imaging can demonstrate the typical findings of acute pancreatitis. Pancreatic pseudocysts develop in approximately 40% of children with traumatic pancreatic injury, and approximately half of these resolve spontaneously.^{1,10}

ERCP, where it is available, can be used to assess for ductal injury if CT findings are equivocal. ERCP has the added benefit of potential intervention as well, with placement of a stent to treat pancreatic duct injury.¹⁵ The routine use of ERCP can also lead to more cases of pancreatic injury being treated nonoperatively.¹⁶

Once pancreatic injury is diagnosed, management depends on the severity and location of the injury and on the presence of associated intra-abdominal injuries.¹⁰ Most patients are treated nonoperatively with bowel rest and total parenteral

nutrition.¹⁷ The decision to intervene surgically is based on hemodynamic instability and the degree of spill of pancreatic fluid into the intraperitoneal or retroperitoneal space.¹⁸ Injury to the proximal pancreatic duct usually is treated conservatively with bowel rest, nasogastric decompression, and hyperalimentation. Transection of the distal pancreatic duct, however, may be treated with distal pancreatectomy with preservation of the spleen.^{10,19}

Abnormal pancreatic enhancement can be seen in the setting of hypoperfusion complex, a rare process seen in young children with hypovolemic shock. This complex tends to occur in those who suffer severe central nervous system or abdominal injury⁵ and have evidence of profound acidemia.²⁰ Imaging findings of hypoperfusion complex include “shock bowel,” with diffusely dilated, fluid-filled bowel with abnormal mural enhancement²; intense enhancement of the pancreas, kidneys, adrenal glands,⁵ and mesentery²; moderate to large intraperitoneal hematomas; and diminished caliber

Figure 121-8 Hypoperfusion complex. The CT scan through the pancreas in a teenager after a motor vehicle accident demonstrates findings of hypoperfusion complex, including intense enhancement of the pancreas and diminished calibers of the aorta and inferior vena cava.

of the abdominal aorta²⁰ and a slitlike inferior vena cava (Fig. 121-8).

Pancreatitis

ACUTE PANCREATITIS

Pancreatitis is an uncommon cause of abdominal pain in children. The clinical diagnosis of acute pancreatitis is based on the presence of upper abdominal pain and tenderness and evaluation of pancreatic enzymes. With a mortality rate⁵ for acute pancreatitis in children as high as 21% and protean clinical presentations, a high level of clinical suspicion is essential for prompt diagnosis.

The causes of acute pancreatitis in children differ significantly from those in adults. In adults, pancreatitis is associated with alcoholism and biliary tract disease in 80% of cases.²¹ The most common cause of acute pancreatitis in children is blunt abdominal trauma,²² followed by infection and drug use.²¹ Numerous drugs and toxins have been implicated in causing acute pancreatitis. The most commonly associated medication in children is the antiseizure drug valproic acid.²³ Infections causing acute pancreatitis in the pediatric population tend to be viral and include the mumps virus,¹⁴ coxsackievirus B, and varicella-zoster virus.²³ Fifteen percent of cases of acute pancreatitis in children are caused by structural anomalies.²⁴ These include congenital anomalies (e.g., pancreas divisum), Crohn's disease, and duodenal ulcers that involve the periampullary region.²⁵ Multisystemic disease, including vasculitis, lupus, sepsis, sickle cell disease, and hemolytic uremic syndrome, accounts for approximately 14% of cases of acute pancreatitis.²⁴ In cases of unexplained pancreatitis, diagnostic considerations, particularly in a young child, should include nonaccidental trauma, inborn errors of organic acid metabolism, hereditary pancreatitis, hemolytic uremic syndrome, and biliary tract disease.⁵ Other causes of pediatric pancreatitis are listed in Table 121-1. In up to 25% of cases, no cause is found.

Plain radiographs are not sensitive for detection of acute pancreatitis, but some reactive findings can be seen (Fig. 121-9). These include atelectasis, elevation of the hemidiaphragms,

TABLE
121-1

Causes of Pediatric Pancreatitis

Trauma

- Motor vehicle collision
- Nonaccidental trauma
- Bicycle handlebar injury

Drugs or toxins

- Antiseizure medications, particularly valproic acid
- Chemotherapeutic agents
- Steroids
- L-Asparaginase
- Acetaminophen
- Sulfasalazine
- Thiazides
- Furosemide

Infections

- Mumps
- Coxsackievirus B
- Varicella-zoster virus
- Ascariasis
- Escherichia coli*
- Fungal infection (immunosuppression)

Structural anomalies

- Pancreas divisum
- Choledochal cysts
- Intestinal duplication cysts
- Periampullary lesions, including Crohn's disease and duodenal ulcers

Metabolic disorders

- Cystic fibrosis
- Hypercalcemia
- Hyperlipidemia

Collagen-vascular diseases

- Lupus
- Vasculitis
- Hemolytic uremic syndrome

Sepsis

Shock

Sickle cell disease

Thalassemia

Figure 121-9 Sentinel loop. The anteroposterior radiograph shows focal dilation of a small bowel loop in the left upper abdomen (arrow), representing a localized ileus caused by peripancreatic inflammation in a 2-year-old boy with abusive traumatic pancreatitis.

Figure 121-10 Acute pancreatitis. **A.** The transverse sonographic image through the pancreas shows a diffusely enlarged pancreas that is echogenic compared with the liver in a 17-year-old girl with a history of thrombotic thrombocytopenic purpura. **B.** Follow-up ultrasound of the same patient 2 weeks later demonstrates interval decrease in the size of the pancreas, with decreased echogenicity compared with the liver.

left pleural effusion, pericardial effusion, and pulmonary edema on chest radiographs.²¹ A sentinel loop in the left upper quadrant or diffuse small bowel ileus (see Fig. 121-9), a dilated transverse colon, or paucity of gas within the descending colon can be seen on abdominal radiographs. Additional findings may include mass effect from a pancreatic pseudocyst and peripancreatic extraluminal gas (if it is associated with an abscess).²¹

Ultrasound is usually the first imaging study performed for the evaluation of suspected pediatric pancreatitis.¹ Enlargement of the pancreas can be seen, either diffuse or focal, usually involving the head¹ (Fig. 121-10). However, there is a wide variation in pancreatic size in children, and there can be overlap between healthy patients and those with pancreatitis.³ The pancreatic echotexture can also become hypoechoic with acute pancreatitis,²¹ but increased echogenicity has also been described.² The most reliable finding in children appears to be dilation of the pancreatic duct.⁹ A dilated duct with poorly defined borders²⁶ can be seen in acute and chronic pancreatitis, with the duct diameter tending to be greater in patients with chronic pancreatitis. The duct diameter associated with pancreatitis is greater than 1.5 mm in children 1 to 6 years of age, greater than 1.9 mm in children 7 to 12 years of age, and greater than 2.2 mm at 13 to 18 years of age.⁶ In mild cases of pancreatitis, the pancreas can appear normal.² Other findings that can be seen on ultrasound include gallstones, biliary sludge, and intrahepatic or extrahepatic biliary ductal dilation.²⁵ Ascites and extrapancreatic fluid collections¹ are frequently observed. Ultrasound is also the modality of choice for follow-up of pancreatitis fluid collections.¹

CT is more sensitive than ultrasound to detect early findings of pancreatitis² and is best for evaluating the severity of pancreatitis and the potential for complications.²¹ CT evaluation of acute pancreatitis in pediatric patients demonstrates a spectrum of findings. These include diffuse gland enlargement with heterogeneous attenuation and enhancement; poorly defined pancreatic margins, peripancreatic fluid, and edema; and fat and soft tissue inflammation (Fig. 121-11).^{5,27} Areas of decreased attenuation and poor contrast enhancement indicate pancreatic necrosis and increased severity of pancreatitis.² A normal pancreas on initial imaging can be seen in up to one third of patients with acute pancreatitis.⁵

Figure 121-11 CT findings of acute pancreatitis. The CT scan shows diffuse enlargement of the pancreas with inflammation of the peripancreatic fat (arrows) in a 7-year-old boy who developed acute pancreatitis after therapy with asparaginase for acute lymphocytic leukemia.

Studies suggest an increasing role for MRI with MRCP in the evaluation of acute pancreatitis, especially given its lack of radiation and excellent soft tissue contrast. MRI may also be more sensitive for detection of acute pancreatitis compared with CT.⁷ MRI demonstrates an enlarged gland with abnormal signal intensity with surrounding inflammation and edema in acute pancreatitis. Specifically, there is loss of the normal intrinsic T1 hyperintensity of the gland and increased T2 signal due to the edema.⁷ MRCP can show congenital anomalies, such as pancreas divisum and abnormal junction of the pancreatobiliary junction, or biliary stones as the etiology of the acute pancreatitis.^{8,25}

ERCP is reserved for children with unexplained recurrent bouts of pancreatitis and patients with a prolonged course to exclude possible structural abnormalities or duct disruption.

ERCP may also be diagnostic and therapeutic in patients with gallstone pancreatitis.²⁵

Approximately half of pediatric patients with acute pancreatitis develop fluid collections outside the pancreas: acute pancreatic fluid, pseudocysts, and abscesses. Of all these, pseudocyst formation is the most common complication of pancreatitis.^{24,26} The most common locations for pseudocyst formation in children are the anterior pararenal space (71%), lesser sac (57%), lesser omentum (50%), and transverse mesocolon.²⁷ Less than 10% of pseudocysts occur within the pancreatic parenchyma in children.²⁸ Pseudocysts with a diameter of less than 10 cm tend to resolve spontaneously. Drainage has been suggested for pseudocysts with a diameter greater than 10 cm or for those less than 10 cm in diameter that do not resolve after 6 weeks.¹⁸ A persistent fluid collection should raise the suspicion of an underlying structural abnormality,²⁷ and further evaluation of the pancreatic duct may be necessary.⁵ Pseudocysts typically are homogeneous in appearance, with an attenuation approaching that of water (Fig. 121-12), unless they are complicated by hemorrhage or infection.¹⁴ Abscesses usually occur more than 4 weeks after the onset of pancreatitis⁵ and can develop from acute pancreatic fluid collections and pseudocysts.

CHRONIC PANCREATITIS

Chronic pancreatitis consists of progressive, irreversible pancreatic destruction due to recurrent pancreatic inflammation that produces fibrosis, fatty degeneration, or calcium deposits.²⁶ It is thought that susceptibility to chronic pancreatitis is influenced by genetic and environmental factors.²⁵ The most common cause worldwide is juvenile tropical pancreatitis, which is associated with pure protein malnutrition and occurs in equatorial, Third World countries.⁵ In the United States, the most common causes are hereditary pancreatitis and cystic fibrosis.²⁵ Hereditary pancreatitis is defined by recurrent attacks of pancreatitis¹⁴ that occur in families during two or more generations without other known predisposing factors.²¹ Most commonly seen in

white children, it is inherited in an autosomal dominant fashion with variable penetrance (40%-80%).¹⁴ The median age at presentation is 10 years.²⁵ Approximately half of the patients develop chronic pancreatitis 10 years after the first bout of acute pancreatitis.²⁵ Complications occur more frequently in patients with hereditary pancreatitis than in those with nonhereditary chronic pancreatitis.²¹ Less common causes include steroid therapy, hyperparathyroidism, pancreas divisum,¹⁴ hypercalcemia,²³ and malnutrition.²⁶

Patients with chronic pancreatitis have chronic, midepigastri abdominal pain.⁵ Pancreatic insufficiency with diabetes is a late-stage complication, occurring when there is less than 10% of residual pancreatic function.^{5,23} Chronic pancreatitis demonstrates increased pancreatic echogenicity sonographically. Irregular contours, with intraparenchymal calcifications and pancreatic duct dilation (Fig. 121-13), are commonly seen.²⁶ CT better characterizes the parenchymal atrophy, duct dilation, and calcifications (Fig. 121-14).⁵ Complications of chronic pancreatitis include recurrent bouts of acute pancreatitis, pseudocyst formation, and increased risk for pancreatic adenocarcinoma.¹⁴ Other major complications include diabetes mellitus, ascites, pleural effusions, portal hypertension, thrombosis of the portal and splenic veins, and exocrine pancreatic insufficiency.²¹

Cystic Fibrosis

Cystic fibrosis is the most common lethal recessive genetic trait in white individuals,² with an incidence of 1 case in 2500 live births.²⁹ Inherited in an autosomal recessive fashion,⁵ cystic fibrosis is a multisystemic disease caused by a variety of mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene.³⁰ The defective gene causes abnormal chloride transport across the membrane of epithelial cells that express CFTR, resulting in abnormally thick exocrine gland secretions that typically affect the lungs, pancreas, and liver²⁶ and also the paranasal sinuses and reproductive tract.²⁹ Although lung

Figure 121-12 Pancreatic pseudocyst. The CT scan through the pancreas shows a large cystic fluid collection in the midabdomen with a mass effect on the stomach that represents a pseudocyst (arrows) in a young patient with a history of pancreatitis.

Figure 121-13 Chronic pancreatitis. The transverse sonographic image of the pancreas reveals dilation of the main pancreatic duct in a 12-year-old girl with chronic pancreatitis.

Figure 121-14 CT findings of chronic pancreatitis. CT demonstrates thinning of the pancreatic parenchyma (straight arrows) with dilation of the pancreatic duct (curved arrow) in a 5-year-old girl with chronic pancreatitis.

Figure 121-15 Ultrasound findings of the pancreas in cystic fibrosis. Transverse ultrasound shows the pancreas to be thin and markedly echogenic as a result of atrophy and fat infiltration (arrows) in a 7-year-old boy with cystic fibrosis.

disease is the leading cause of morbidity and mortality in persons with cystic fibrosis,³¹ improved treatment of lung disease has resulted in longer survival and increased morbidity from involvement of other organs,²⁹ including the pancreas.

The tenacious pancreatic secretions of cystic fibrosis cause obstruction of pancreatic ducts with upstream acinar and ductal distention and end-stage atrophy of acinar tissue.⁵ If it is severe enough, the degeneration eventually results in replacement of pancreatic parenchyma with fibrosis and fat.^{5,26} Cystic fibrosis is responsible for 85% to 90% of exocrine pancreatic insufficiency in children.² It occurs at or soon after birth as a result of chronic obstruction.³⁰ Only 10% to 15% of patients maintain enough pancreatic function to avoid steatorrhea. Endocrine dysfunction in cystic fibrosis is less common, with 30% to 50% of cystic fibrosis patients demonstrating glucose intolerance and 13% of adult patients having diabetes.³¹

Several patterns of pancreatic changes have been described in cystic fibrosis: complete replacement of the pancreas by fibrofatty tissue with enlargement of the pancreas, partial replacement of the pancreas by fibrofatty tissue, complete pancreatic atrophy without fatty replacement, diffuse pancreatic fibrosis, and cystic transformation of the pancreas.²⁹ Pancreatic calcifications and small pancreatic cysts that do not exceed several millimeters in diameter are not uncommon imaging features in cystic fibrosis.²⁹ Pancreatic cystosis is a usual complication of cystic fibrosis, with larger cysts distributed throughout the gland.²⁹ These true cysts are caused by obstruction of pancreatic ducts by tenacious secretions, resulting in upstream dilation.²⁹ Pancreatic calcifications are typically seen in dilated pancreatic ducts after ductal and ductular obstruction by calcium-rich inspissated material.³² Although cystic fibrosis is one of the most common causes of chronic pancreatitis, acute

pancreatitis is not a common manifestation because there is generally not enough functioning residual pancreatic tissue to mount the inflammatory reaction.^{5,25} Acute pancreatitis should be suspected, however, if there is enlargement of the pancreatic head.¹

The sonographic findings of cystic fibrosis include increased pancreatic echogenicity due to fatty replacement and decreased pancreatic size due to pancreatic atrophy (Fig. 121-15).²⁹ Other findings can include calcifications and single or multiple cysts.² In the setting of pancreatic cystosis, multiple anechoic lesions are seen with smooth, thin walls without nodules and enhanced through-transmission.

CT evaluation of the pancreas in patients with cystic fibrosis demonstrates diffuse, low attenuation throughout an enlarged pancreas, consistent with fatty replacement (Fig. 121-16). When complete atrophy is present, it is seen as a small pancreas with soft tissue attenuation and with no enhancement after administration of contrast material.²⁹ Other findings may include parenchymal calcifications and the cysts of pancreatic cystosis.²

MRI demonstrates complete fatty replacement of the pancreas, which is manifested as an enlarged pancreas with high signal intensity on T1-weighted images. Fibrosis of the pancreas is seen as low signal intensity on T1- and T2-weighted images, without the high signal intensity of fat on T1-weighted images.^{29,32} A disadvantage of pancreatic MRI is the inability to reliably demonstrate small calcifications.²⁸ On MRCP, the main pancreatic duct usually is not well delineated in cystic fibrosis because of pancreatic duct narrowing.³² When cysts are present, they have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images with thin, smooth walls that have low signal intensity.²⁹

Figure 121-16 CT findings of the pancreas in cystic fibrosis. **A** and **B**. CT demonstrates fatty replacement of the pancreas (arrows) in a teenaged girl. The patient also has a nodular liver from hepatic fibrosis and has splenic varices (arrowheads) and splenomegaly from portal hypertension.

Figure 121-17 Shwachman-Diamond syndrome. CT shows the loss of pancreatic parenchyma from atrophy and infiltration of the pancreas by fat (arrows) in a young boy with Shwachman-Diamond syndrome.

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome is the second most common cause of exocrine pancreatic insufficiency in childhood after cystic fibrosis, with a clinical spectrum from mild to nearly complete absence of exocrine function.³³ It is inherited in an autosomal recessive fashion, and other associated manifestations include skeletal and bone marrow abnormalities. These patients have exocrine pancreatic insufficiency with a normal sweat test result,³⁴ allowing the syndrome to be distinguished from cystic fibrosis.⁵ Clinically, patients with Shwachman-Diamond syndrome present with steatorrhea during infancy.²¹ Unlike with cystic fibrosis, the clinical condition of patients with Shwachman-Diamond syndrome tends to improve with age.⁵ On pathologic examination, there is fatty infiltration of the pancreas with reduction of the acini, but the islets and ducts are preserved^{1,21,34} (Fig. 121-17).³³ Initially, the pancreas may be enlarged, but the size later becomes normal or slightly small.¹⁴

Patients may demonstrate hepatomegaly or splenomegaly, which may be caused by infection or malnutrition.³³ Pancreatic calcifications and cysts are not associated with Shwachman-Diamond syndrome, which distinguishes this disease from cystic fibrosis.⁵

Nesidioblastosis

Nesidioblastosis, also known as persistent hyperinsulinemic hypoglycemia of neonates and infants and as diffuse adenomatosis, is a congenital anomaly characterized by persistence of the fetal state of the pancreas. On pathologic examination, there is proliferation and persistence of nesidioblasts, cells that differentiate from ductal epithelium.²⁶ These nesidioblasts produce insulin, and patients present with symptoms of hypoglycemia, usually detected in the newborn and infant stage.^{1,26} Diagnosis of nesidioblastosis is made by the persistence of symptomatic hypoglycemia with inappropriately high levels of insulin and with the inappropriate response to intravenous glucagon.³⁵ The diagnosis can also be made by selective venous sampling in pancreatic veins, evaluating for elevated insulin levels.³⁶ Two forms have been identified, one with focal adenomatous hyperplasia and the second with diffuse B-cell abnormalities.³⁶ Ultrasound of the pancreas sometimes demonstrates diffuse increased echogenicity and increased size of the pancreatic head, body, and tail in the diffuse form. The lesions in the focal form are not well visualized radiologically.³⁶ Nearly total pancreatectomy is necessary in the setting of persistent hypoglycemia with the diffuse form; with the focal form, only that particular lesion needs to be resected.³⁷

Pancreatic Masses

CONGENITAL CYSTS

True congenital cysts of the pancreas are rare and are the result of anomalous development of the pancreatic ducts.^{26,38} During prenatal ultrasound scanning, the cysts may be manifested incidentally or may be associated with polyhydramnios. Postnatally, the cysts can be diagnosed at any age.¹ Patients are usually asymptomatic, and the cysts are found incidentally.³⁸ There is a

Figure 121-18 Pancreatoblastoma. **A.** CT demonstrates a large, well-defined mass in the head of the pancreas (arrows) of a young boy with pancreatoblastoma. **B.** CT scan through the liver demonstrates multiple, heterogeneous masses within the hepatic parenchyma consistent with metastatic disease.

female predominance.³⁸ Congenital pancreatic cysts have an epithelial lining, are usually singular and unilocular, and are typically located in the body or tail of the pancreas.^{5,38} Communication with the pancreatic duct is rare.³⁸ On sonography, congenital pancreatic cysts usually are anechoic and may range in size from microscopic up to 5 cm in diameter. On CT, the cysts generally have low attenuation and demonstrate no mural enhancement.³⁸ When they are multiple, congenital cysts may be seen in association with a variety of syndromes, including Beckwith-Wiedemann syndrome, autosomal dominant polycystic kidney disease (ADPKD), and von Hippel–Lindau disease (VHL).²⁶

NEOPLASMS

Tumors of the pediatric pancreas are extremely rare. They are classified as epithelial or nonepithelial in origin; the epithelial tumors are further subdivided into exocrine and endocrine tumors.³⁷ In the pediatric population, the most common exocrine tumors are pancreatoblastoma and adenocarcinoma. Endocrine tumors can be hormonally functioning or nonfunctioning. Mesenchymal tumors of the pediatric pancreas are even rarer.

Exocrine Tumors of the Pancreas

Pancreatoblastoma. Pancreatoblastoma, also known as infantile carcinoma of the pancreas, is the most common pancreatic neoplasm of childhood.²⁸ This rare epithelial tumor,¹⁴ which is often misdiagnosed as neuroblastoma or hepatoblastoma,⁵ has a 2:1 male-to-female ratio.^{2,28} The mean age at diagnosis is 4 years, but it can be manifested at any time from the newborn period to adulthood.² It is associated with Beckwith-Wiedemann syndrome^{2,28} and has an increased incidence in East Asia.² Patients usually present with abdominal distention or with a large, palpable abdominal mass. The mass may be associated with nonspecific symptoms, including failure to thrive, epigastric pain, anorexia, vomiting, diarrhea, and weight loss.²⁸ Obstructive jaundice may also be present. The serum α -fetoprotein level is elevated in 25% to 55% of patients, and the tumor may secrete adrenocorticotrophic hormone.^{2,39}

Pancreatoblastoma can be located anywhere in the pancreas; it may be exophytic or may entirely replace the pancreas.²⁸ The mass tends to be large at the time of presentation, with a diameter of 7 to 18 cm. It is usually solitary, well defined, and surrounded by a fibrous capsule.^{14,28} Metastases are most

commonly seen in the liver but may also occur in regional lymph nodes, lungs, and, rarely, bone.³⁹ Local invasion of the bowel and peritoneal cavity as well as of adjacent structures like the spleen, kidney, and adrenal gland can also occur.^{28,39} When metastatic disease is present, the prognosis is typically poor.²

In general, imaging demonstrates a solid mass with an appearance suggestive of but not specific for pancreatoblastoma.¹ The pancreatoblastoma usually is large and well defined, and it may be lobulated.⁵ Sonography demonstrates a well-demarcated, heterogeneous mass with both solid and cystic components.³⁷ A predominantly hypoechoic solid mass may also be seen.³⁹ CT usually demonstrates a mass with heterogeneous contrast enhancement and areas of low attenuation, suggestive of cystic necrosis (Fig. 121-18).³⁹ Metastases to the liver tend to be hypodense and may also contain areas of central necrosis.³⁹ On MRI, pancreatoblastoma is low to intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images.³⁷ Vascular encasement of the mesenteric vessels and the inferior vena cava may develop, and calcifications can be present, which may make differentiation from neuroblastoma difficult.³⁹

Given the nonspecific imaging findings of pancreatoblastoma, the diagnosis is generally established by percutaneous biopsy.¹ Treatment consists of surgical excision, with chemotherapy administered for metastatic disease.²⁸ Radiation therapy is used for local recurrence or incomplete resection.^{1,40} Although some patients are cured with excision alone, recurrence has been described in up to 60% of patients.⁴⁰

Adenocarcinoma. Adenocarcinomas, both the ductal and acinar types, are extremely rare in children. Of these, the acinar type is more frequently seen in children and is pathologically related to pancreatoblastoma.³⁷ The mass can occur anywhere in the pancreas and tends to be manifested with symptoms related to local tumor expansion or metastases.² Metastases are commonly present at the time of diagnosis.²⁶ Imaging demonstrates a well-circumscribed, nodular mass with areas of necrosis.² On sonography, the mass is usually cystic or has mixed solid and cystic components.²⁶ CT imaging demonstrates hemorrhagic and cystic areas with heterogeneous enhancement.⁵ Calcification can also be seen.

The ductal type typically occurs in adults but has been reported in teenaged patients.²⁸ It is most commonly located in the head of the pancreas. Patients present with pain and weight loss, and more than half have obstructive jaundice. Imaging

demonstrates a small hypovascular mass, often with dilation of the main pancreatic duct and common bile duct proximal to the mass.²

Endocrine Tumors of the Pancreas

Islet Cell Tumors. Islet cell tumors can be classified as functioning or nonfunctioning endocrine tumors.² If they are functioning, islet cell tumors are associated with hypoglycemia (insulinoma) or Zollinger-Ellison syndrome (gastrinoma); ACTHomas and VIPomas are less common in children.³⁷ Nonfunctioning islet cell carcinoma is much more common in the pediatric population than in adults and usually is manifested as an abdominal mass. Metastases are common at presentation because of the delay in diagnosis of this nonfunctioning tumor.²⁸

METASTATIC DISEASE

Metastatic disease to the pancreas is more common than primary pancreatic neoplasms in the pediatric population. Burkitt's lymphoma is the most common cause of metastases (Fig. 121-19). The mean age at the time of presentation is 11 years, and the clinical picture is nonspecific.²⁶ Sonographic evaluation may demonstrate a solitary lesion, diffuse infiltration of the pancreas, or multiple lesions, which usually are solid, well defined, and hypoechoic.²⁶ Metastases can also be seen from other malignant neoplasms, including primitive neuroectodermal tumor, Kaposi's sarcoma, and neuroblastoma. Neuroblastoma usually involves the pancreas through lymphatic spread or by direct invasion.⁵

Miscellaneous Processes

VON HIPPEL-LINDAU DISEASE

VHLD is an autosomal dominant disorder with variable penetrance (80%-100%)^{41,42} and variable delayed expressivity; it

usually becomes clinically apparent in the second or third decade.⁵ The clinical manifestations of VHLD are broad and include both benign and malignant lesions in multiple organ systems; the most common manifestations are pancreatic cysts and tumors, renal cysts and clear cell carcinomas, retinal and cerebellar hemangioblastomas, and pheochromocytomas.⁴³ Renal cysts are the most common abdominal lesions of VHLD, seen in approximately 76% of patients.⁴⁴ These cysts can range from single to innumerable, simulating polycystic kidney disease.⁴¹

Cysts, which range from the typical simple pancreatic cyst⁴⁴ to cystic replacement of the pancreas, are the most common pancreatic lesion of VHLD.⁴¹ Cysts have been described in 30% to 50% of VHLD patients on imaging in some series,^{5,44} and an autopsy series described these cysts in approximately 72% of patients with known VHLD.⁴⁴ The cysts tend to occur in the body and tail of the pancreas⁵ (Figs. 121-20 and 121-21) and typically are small. Diabetes has been described in patients with extensive cystic replacement of the pancreas,⁴⁴ and large cysts may cause obstruction of the common bile duct.¹⁴ Other lesions involving the pancreas in VHLD include nonfunctioning islet cell tumors,⁴⁴ hemangioblastomas,⁴¹ serous cystadenoma (i.e., microcystic adenoma), and adenocarcinoma of the ampulla of Vater.^{2,42} Pancreatic carcinoma has been described in families with VHLD and may be a source of mortality in some families.⁴⁴

BECKWITH-WIEDEMANN SYNDROME

Beckwith-Wiedemann syndrome is a rare disorder characterized by the classic triad of omphalocele, macroglossia, and gigantism. Although it can be familial, with autosomal dominant inheritance, variable expressivity, and reduced penetrance, most cases are sporadic.⁴⁵ Patients may demonstrate hemihypertrophy and various degrees of visceromegaly of the kidneys, liver, pancreas, and adrenal glands (Fig. 121-22).² Cysts have also been reported in the kidneys and rarely in the adrenals.⁴⁵ Patients are also at increased risk for development of malignant neoplasms.⁴⁵

Figure 121-19 Lymphoma infiltrating the pancreas. The CT scan shows enlargement of the pancreas with infiltration by nodular soft tissue representing nodal enlargement (straight arrows) in a 7-year-old boy with Hodgkin's lymphoma. Notice the blood vessel (curved arrow) coursing through this region and the retroperitoneal adenopathy extending into the left renal hilum (arrowheads).

Figure 121-20 Pancreatic cysts in von Hippel-Lindau disease. The CT scan demonstrates numerous, small cysts within the pancreas in a young woman with von Hippel-Lindau disease.

Figure 121-21 von Hippel–Lindau disease. **A.** CT scan through the pancreas demonstrates small cysts within the tail of the pancreas (arrows) in a young woman with von Hippel–Lindau disease. A hyperenhancing mass within the spinal canal is consistent with a hemangioblastoma (arrowhead). **B.** CT scan through the level of the kidneys demonstrates a heterogeneous mass within the left kidney consistent with a renal cell carcinoma (arrows).

Figure 121-22 Pancreatic enlargement in Beckwith-Wiedemann syndrome. Axial-view, turbo T2-weighted MRI shows diffuse enlargement of the pancreas (arrows), which has normal signal intensity, in a 19-month-old girl with Beckwith-Wiedemann syndrome being observed for hepatoblastoma.

Figure 121-23 Pancreatic cysts in autosomal dominant polycystic kidney disease. The CT scan shows a pancreas (straight arrows) that is nearly replaced by large cysts in a 12-year-old boy with autosomal dominant polycystic kidney disease. The cysts also are demonstrated in the liver (curved arrows), and both kidneys are enlarged and contain many cysts (arrowheads).

Beckwith-Wiedemann syndrome is associated with a high risk of neonatal hypoglycemia.⁴⁵ Hypoglycemia often occurs in the first few days of life, and if it is severe enough, it may cause mental retardation.⁴⁵ Long-term prognosis depends on the occurrence of neoplasms, which are usually intra-abdominal.⁴⁶ Associated malignant neoplasms include Wilms' tumor⁴⁵ and pancreatoblastoma.²

Findings suggestive of Beckwith-Wiedemann syndrome on prenatal ultrasound include fetal macrosomia and anterior abdominal wall defects, most commonly omphalocele, hepatomegaly, nephromegaly, and macroglossia.⁴⁵ Because of the increased risk of intra-abdominal malignant neoplasms, routine abdominal ultrasounds are recommended at least every 4 months until the age of 7 or 8 years.⁴⁷

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD is an autosomal dominant disorder with nearly 100% penetrance. Although renal cysts are the dominant feature, cysts can be seen in additional abdominal organs, including the pancreas, liver, spleen, and adrenal glands.² Pancreatic cysts occur in approximately 10% of patients with ADPKD,² and when pancreatic cysts are present, renal cysts usually are present.⁵ Sonography and CT usually demonstrate simple cysts, which can be multiple, are usually small, and may be present anywhere in the gland.⁴⁸ The cystic changes are typically not as severe as those involving the kidneys or liver, but cystic transformation of the pancreas has been described (Fig. 121-23).^{26,49}

Infarction

Sickle Cell Disease

Sequestration
Normal Islands of Splenic Tissue
Functional Asplenia

Peliosis

Gaucher's Disease

Histiocytic Syndromes

Splenic Histology and Function

Splenic tissue is composed of red pulp and white pulp. The red pulp is composed of vascular sinusoids, and the white pulp is composed of lymphoid follicles with white blood cells.¹ The proportion of white pulp relative to red pulp increases with age and antigenic stimulation.^{1,2} Mononuclear phagocytic cells of the red pulp remove abnormal or senescent red blood cells from circulation.^{3,4}

The radiographic appearance of the spleen depends on the imaging modality, age of the patient, splenic composition and

size,¹ and timing of intravenous administration of contrast agents.⁵ The spleen has the shape of a curved wedge and may have normal clefts, notches, or lobules.^{3,6}

On ultrasound, the normal spleen has a homogeneous echotexture that is hyperechoic to the pediatric kidney and isoechoic or hyperechoic to the liver on gray-scale images (Figs. 122-1 and 122-2). The parenchyma is exceptionally vascular on color flow Doppler imaging.³

Precontrast computed tomography (CT) examination of the normal spleen demonstrates uniform parenchymal attenuation that is slightly less than that of the normal liver.² On contrast-enhanced examinations, the spleen's appearance depends on the timing of the intravenous administration of the contrast bolus and image acquisition. Transient heterogeneous enhancement of the spleen is presumed to result from differences in relative flow rates through the red and white pulp. The mean time of initial visualization of the heterogeneity after infusion of the contrast agent is 19.2 seconds (range, 9-44 seconds). Normal transient heterogeneity persists 70 seconds after administration of the contrast agent in only 6% of children.⁵ The patterns as seen on contrast-enhanced CT and magnetic resonance imaging (MRI) examinations are varied and include arcs, stripes (Fig. 122-3), and focal areas of relatively delayed perfusion. Heterogeneous areas in the spleen on images acquired more than 70 seconds after the administration of contrast material may indicate an abnormality.⁵

The tissue characteristics related to the ratio of red and white pulp probably dictate the signal intensity on MRI. In the neonate, the lymphoid tissue of the white pulp is not well developed, and the spleen is composed primarily of the vascular sinusoids of the red pulp. In the first week of life, the spleen usually is isointense or hypointense relative to the liver on T1- and T2-weighted, spin-echo images (Fig. 122-4A, B).¹ With the maturation of high cellular water content lymphoid tissue, the spleen becomes minimally hyperintense relative to the liver on T2-weighted images at approximately the second week of life.⁶ When the child is 1 month old, the spleen is moderately hypointense relative to the liver.¹ There is a relative increase in the size and number of lymphoid follicles and a relative decrease in the extent of red pulp up to the age of 7 months (Fig. 122-4C, D). After the child is 8 months old, the signal characteristics of the pediatric spleen are the same as in the adult.¹ As on contrast-enhanced CT, the spleen often shows heterogeneous enhancement during the arterial phase of dynamic contrast-enhanced MRI.^{7,8} It has been theorized that the decreased signal intensity of the spleen relative to the liver in patients after chemotherapy, with or without associated blood transfusions, may result from reduction or elimination of the white pulp's high water content and lymphoid tissue.⁹

Nuclear medicine studies to evaluate the spleen include technetium ^{99m}Tc sulfur colloid scintigraphy and ^{99m}Tc-denatured (heat-damaged) red cell scintigraphy. Sulfur colloid is phagocytosed by the reticuloendothelial cells of the spleen

Figure 122-1 Normal spleen on ultrasound. Sonogram of a normal pediatric spleen demonstrates a uniform parenchymal echotexture, smooth outer capsular surface (arrowheads), and concave hilum (arrow).

Figure 122-2 Normal spleen on ultrasound. Sonogram of a normal pediatric spleen demonstrates the normal uniform echotexture of the spleen (arrow) that is hyperechoic to the normal kidney (arrowhead).

and liver, and denatured red cells are sequestered in the spleen. Indications for splenic scintigraphy include evaluation of abdominal trauma, splenomegaly, and left upper quadrant mass; search for accessory spleens or splenosis; and assessment of infarction, functional asplenia, polysplenia, and the heterotaxy syndrome.¹⁰

Figure 122-3 Splenic MR perfusion artifact. Axial view, volumetric interpolated breath-hold examination (VIBE) MR image obtained during administration of contrast material demonstrates transient splenic parenchymal perfusion patterns, including arcs and stripes.

Spleen Size

The spleen increases in length and volume as the child grows. Splenic length is typically measured sonographically in the coronal plane through the hilum, from the dome of the spleen to the inferior tip.¹¹ Upper limits of normal for age are 6 cm at 3 months, 6.5 cm at 6 months, 7 cm at 12 months, 8 cm at 2 years, 9 cm at 4 years, 9.5 cm at 6 years, 10 cm at 8 years, 11 cm at 10 years, 11.5 cm at 12 years, and 12 cm at and beyond 15 years for girls and 13 cm for boys 15 years and older.¹¹ Secondary imaging signs of splenomegaly include extension of the spleen below the inferior margin of the left kidney or the right hepatic lobe, medial extension to the aorta, and loss of the concavity of the hilum (Fig. 122-5).³

Congenital Abnormalities

SPLENULES

Splenules are congenital rests of normal splenic tissue that form when mesenchymal cells fail to fuse with the rest of the splenic mesenchyme.^{12,13} A splenule is also known as an accessory spleen, supernumerary spleen, or splenunculus. Splenules are typically located near the main splenic hilum anteriorly or posteriorly but are rarely lateral to the main spleen and have not been documented superior to the main spleen.¹⁴

Splenules are circumscribed, round, oval,¹³ or triangular, and they are homogeneous with and without enhancement (Fig. 122-6).¹⁴ Splenules vary in size from millimeters to centimeters, usually less than 3.2 cm in diameter, and are capable of significant hypertrophy.^{4,13,15}

Splenic artery supply to a splenule may be visible on CT. On CT, 16% of people have one to three accessory spleens,¹⁴ and the presence of 10 splenules has been described.¹⁶ Splenules are seen in 10% to 30% of people at surgery or autopsy.¹⁵ Subcentimeter splenules may have lower attenuation than the main spleen because of volume averaging with surrounding fat and the CT collimation used.¹⁴

Figure 122-4 Normal spleen: MR findings. MRI demonstrates the normal change in signal intensity of the spleen (arrows) relative to the liver in a 9-day-old neonate (**A** and **B**) and in the same child at 12 weeks (**C** and **D**). In the T1-weighted image (**A**) and fast spin-echo T2-weighted image (**B**) of the 9-day-old infant, the neonatal spleen has relatively lower signal intensity, particularly on T2-weighted sequences, because of the higher ratio of vascular red pulp to white pulp. The T1-weighted image (**C**) demonstrates MR findings for the same child at age 12 weeks. As the lymphoid tissue of the white pulp matures, the spleen (arrows) becomes moderately hyperintense to the liver on fast spin-echo T2-weighted images (**D**).

Figure 122-5 Splenomegaly: MR findings. The spleen is grossly enlarged, extending inferior to the cirrhotic right hepatic lobe. Note the splenic hilar varices (arrow) and punctate hypointense splenic siderotic nodules (arrowhead) on this T2-weighted coronal image.

Splenules need to be removed if the patient is undergoing therapeutic splenectomy for a hematologic disease because the residual splenic tissue can be responsible for recurrent disease.¹⁶⁻¹⁸ Accessory spleens may resemble lymphadenopathy or neoplasm if they are situated near the greater curve of the stomach,¹⁵ in the left adrenal,¹⁹ or within the pancreatic tail.^{15,20} Splenules may become symptomatic if they twist.²¹

POLYSPLENIA AND ASPLENIA

Multiple spleens (i.e., polysplenia) or absence of the spleen (i.e., asplenia) at birth can be associated with multiple congenital

Figure 122-6 Normal splenules. In the contrast-enhanced CT scan of an 18-year-old girl with abdominal pain, two splenules are seen at the hilar surface (arrows). They are 2.0 × 2.3 cm in the greatest dimension. The splenules have the same attenuation as the normal spleen on this 5-mm, axial view, contrast-enhanced CT image.

anomalies under the heading of heterotaxy or situs ambiguus.²² In polysplenia, multiple small spleens are always seen on the same side as the stomach²² because of the origin of splenic tissue from the dorsal mesogastrium (Fig. 122-7).¹² Polysplenia is often associated with an interrupted inferior vena cava with azygos continuation, bilateral left-sidedness, and congenital heart disease.²² There may also be associated absence of the gallbladder, biliary atresia, preduodenal portal vein,²² and malrotation of the bowel.²²⁻²⁴

Asplenia is the absence of splenic tissue and is associated with bilateral right-sidedness and complex cyanotic heart disease.^{6,25} There is an association with gallbladder duplication,^{6,8} midgut malfixation or malrotation, and microgastria.²⁶

Nuclear scintigraphy with ^{99m}Tc-sulfur colloid or heat-damaged ^{99m}Tc-labeled erythrocytes can evaluate for the presence or absence of splenic tissue.²⁵

Figure 122-7 Polysplenia. Axial view, contrast-enhanced CT shows multiple spleens of various sizes in the retrogastric area of the left upper quadrant (arrows). The azygos vein is enlarged (arrowhead), and the intrahepatic inferior vena cava is absent.

WANDERING SPLEEN

The spleen is primarily supported by the gastrosplenic and splenorenal ligaments.^{3,12,27,28} If the support ligaments are absent or lax, the spleen may be ectopic from its normal position and is referred to as a wandering spleen. It is rare in children.²⁷⁻²⁹ The degree of ectopia is limited by the length of the vascular pedicle.³⁰ The absence of the spleen in its usual position and presence of a soft tissue mass elsewhere with the imaging characteristics of the spleen characterize this entity (Fig. 122-8). There may be a history of intermittent abdominal pain^{27,31} or an intermittently palpable abdominal mass.⁶ The child with torsion of a wandering spleen usually presents with an acute surgical abdomen.^{27-29,32}

Ultrasound evaluation of torsion of the wandering spleen may demonstrate areas of hyperechoic hemorrhage and hypoechoic infarction and congestion. Early, the gray-scale echotexture may be preserved with or without splenomegaly,³³ and color Doppler examination may demonstrate splenic vein occlusion or stasis with preserved arterial flow and intraparenchymal flow. As the torsion persists, arterial inflow eventually decreases or ceases to be detectable.^{33,34}

On CT, the spleen with torsion may be heterogeneously enhancing and have decreased attenuation, depending on the extent of perfusion. The enhancing hilar vessels twist with the interpositional hilar fat and yield a whorled or banded appearance (Fig. 122-9).²⁷ On ultrasound examination, twisted hilar vessels appear as a splenic hilar mass, which may be an important finding for cases in which the diagnosis is not yet made and the twisted spleen is not ectopic.³³ The wandering spleen is associated with deficiency of anterior abdominal wall musculature³⁴ and is rarely reported with prune-belly syndrome.³⁵

After diagnosis of torsion of a wandering spleen, if the spleen is not infarcted, splenopexy may be performed in an effort to preserve splenic function by preventing future torsion.^{28,29,31,33}

Figure 122-8 Ectopic wandering spleen. A plain radiograph demonstrates gaseous distention of the colon in the left upper quadrant, with no mass effect in the expected location of the spleen. In the midabdomen, the ectopic spleen (arrowheads) displaces the bowel, as confirmed on cross-sectional imaging. Air-fluid levels are seen in the small bowel.

SPLENOGONADAL FUSION

The splenic anlage and ipsilateral gonadal anlage have a close developmental relationship and may fuse, forming a long, *continuous* cord from the gonad cephalad to the main spleen.⁴ The connection to the main spleen may be totally or partially fibrous³⁶ and is associated with cryptorchidism.⁴ Alternatively, a portion of the splenic tissue may separate from the main spleen (*discontinuous*) and descend with the gonad,⁴ known as splenogonadal fusion.

Male children with splenogonadal fusion typically present with a painless testicular mass.³⁶ Splenogonadal fusion should be considered preoperatively in evaluation of a scrotal mass because failure to do so may result in unnecessary orchiectomy. The ectopic splenic tissue attached to the testicle mimics testicular duplication on ultrasound and has been described as an encapsulated, homogeneous extratesticular mass that is isoechoic with the normal testis and shows no hyperemia on color Doppler ultrasound. The presence of ectopic splenic tissue can be confirmed with nuclear ^{99m}Tc-sulfur colloid scintigraphy.⁴

Cystic Lesions

TRUE CYSTS AND PSEUDOCYSTS

True cysts, such as congenital or epithelial cysts and echinococcal cysts, have an epithelial cell lining, but pseudocysts do not.^{6,7}

Figure 122-9 Splenic torsion. **A.** Torsion of the wandering spleen demonstrates absence of enhancement (arrow) on this contrast-enhanced CT coronal reformation. **B.** Note the whorled appearance of the splenic hilar vessels (arrow) and the lack of enhancement of the spleen parenchyma.

Figure 122-10 Epidermoid cyst. Contrast-enhanced CT demonstrates a large, intrasplenic cystic mass with a relatively thin wall. Notice the septa or trabeculae (arrows).

It is not possible to reliably differentiate between true cysts and pseudocysts by imaging.³⁷

Epithelial cysts can be further categorized as mesothelial, epidermoid, or dermoid. Epidermoid cysts are lined by stratified squamous epithelium, which macroscopically appears coarsely trabeculated.^{37,38} Epidermoid cysts may be familial, are often several centimeters in diameter, and have a tendency to rupture.³⁸

Epidermoid cysts on ultrasound appear as relatively thin walled, anechoic lesions that do not change over time. Mural calcification is seen in 10% of cases, although it is seen more often in acquired pseudocysts.³⁷ There may be septations and wall trabeculation, which are seen more often in true cysts.³⁷ The fluid may have some internal echoes caused by cholesterol crystals, inflammatory debris, or blood products from prior hemorrhage.³⁷ On CT and MRI, cysts follow fluid attenuation and signal character, with or without septations and calcification (Fig. 122-10).^{6,39,40} These cysts show no central or rim enhancement.⁷

Echinococcal cysts are true cysts. They can have peripheral calcification and often appear to have multiple septa.^{7,41} In echinococcal cysts, there may be internal areas of increased attenuation on CT due to dense debris, also known as hydatid sand. Peripherally located small daughter cysts may be present.⁴¹

Acquired pseudocysts, most often post-traumatic, are more common than true cysts.^{41,42} They are indistinguishable on imaging from true cysts and may have mural calcification,^{41,42} but septa are uncommon.⁴¹

LYMPHATIC MALFORMATIONS

Lymphatic malformations of the spleen, also known as lymphangiomas, are congenital and are composed of dilated lymphatic channels.^{43,44} Despite their rarity in the spleen,⁴⁵ lymphatic malformations are the second most common benign splenic lesion.⁸ They are not neoplastic, and their growth is commensurate with that of the child.^{46,47} An abrupt change in lymphatic pressure or flow, infection, or hemorrhage into the lesion can cause an abrupt increase in size.⁴⁶⁻⁴⁸ They are frequently asymptomatic and are found incidentally (Fig. 122-11).³⁹

The lymphatic channels and compartments are lined by a single layer of flattened endothelial cells and contain lymphatic fluid.⁴⁵ They can be solitary, or they may be associated with other lymphatic malformations of the viscera, bone, or soft tissues.^{45,49}

On imaging, lymphatic malformations of the spleen appear similar to lymphatic malformations elsewhere in the body, with a multiloculated, cystic configuration.⁴⁵ On ultrasound, there are well-defined, hypoechoic or anechoic spaces of various sizes, typically with septations and proteinaceous debris that may produce internal echoes.^{43,45,49} Radionuclide ^{99m}Tc-sulfur colloid scans show a focal area of decreased uptake.⁴⁵

On CT, lymphatic malformations are hypodense with non-enhancing discrete areas⁴⁹ that are often subcapsular, but they can be diffuse.^{43,50} The walls and septa may faintly enhance after administration of contrast material.^{44,50}

On MRI, the cystic areas are usually hypointense on T1-weighted images and hyperintense on T2-weighted images.^{7,44,49} They may appear hyperintense on T1-weighted images because of proteinaceous contents or prior hemorrhage, with or without fluid-fluid levels on T2-weighted sequences.^{8,44}

Figure 122-11 Lymphatic malformation. **A.** Multiple, nonenhancing, well-defined, low-attenuation, intrasplenic cystic lesions were incidentally found in a 3-year-old child. Lesions were stable during 1 month. Subsequent PET/CT examination showed no evidence of hypermetabolic features. Multiple lymphatic malformations were diagnosed at splenectomy. **B.** Contrast-enhanced CT in a different child demonstrates multiple septations (arrowheads) within this single, large lymphatic malformation that originates within the spleen. Although the septations may enhance, the cystic spaces of lymphatic malformations do not.

The cystic areas do not enhance, but the septa may enhance on the delayed phase images.⁷

Benign Lesions

HEMANGIOMAS

Before the classification by Mulliken and Glowacki,⁵¹ hemangiomas and vascular malformations had variable nomenclature in the literature, leading to classification confusion. The International Society for the Study of Vascular Anomalies (ISSVA) has subsequently established guidelines based on the histopathology, clinical course, and treatment of these lesions.⁵² Despite the criteria outlined in the ISSVA guidelines, lesions referred to as hemangiomas are the most common benign lesions of the spleen.^{13,50,53,54}

The imaging appearance of pediatric splenic hemangiomas on ultrasound, CT, and MRI is variable, as reported in the literature.^{13,41,50,53-56} This probably reflects the widespread use of inaccurate terminology in the medical literature, as some authors were likely describing vascular neoplasms, whereas others were describing vascular malformations.^{52,57}

Hemangiomas are benign and usually asymptomatic solid neoplasms composed predominantly of a mass of endothelial cells.^{44,52} Proliferating hemangiomas may cause clinical complications by location, mass effect, or platelet sequestration. They have an initial proliferative phase during the first year of life, followed by an involution phase.^{44,58} In the proliferative phase, a hemangioma is seen on MRI as a solid, lobulated, soft tissue mass that is isointense or hypointense to muscle on T1-weighted images and hyperintense on T2-weighted images, with uniform contrast enhancement. Feeding arteries and draining veins may be seen and can demonstrate prominent flow voids.^{44,58} During involution, there is fatty replacement of the neoplasm. There is a variable increase in signal on T1-weighted images and decreased signal on T2-weighted images.⁴⁴

VASCULAR MALFORMATIONS

Vascular malformations are congenital lesions composed of some combination of arterial, capillary, venous, and lymphatic

channels. They are described by their flow characteristics (i.e., high or low flow).^{44,52,58} Venous malformations are low-flow vascular malformations that were formerly known as cavernous hemangiomas, varicose hemangiomas, or lymphangiohemangiomas.⁴⁴ Vascular malformations are distinguished from vascular neoplasms, such as hemangiomas, by the lack of increased endothelial cell turnover.⁵² They are composed of endothelial cell-lined channels, with interconnecting venous spaces and various connections to normal or dysplastic draining veins. The spaces are filled with blood, and there is no true solid mass. They may contain phleboliths. They have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. The walls of the vascular spaces may appear as septations that do not enhance, whereas the vascular spaces do enhance if they are not thrombosed. Fluid-fluid levels may be seen. Phleboliths appear as signal voids on MRI.⁴⁴

HAMARTOMA

Hamartomas are rare, non-neoplastic, disorganized mixtures of normal splenic components.^{6,55,59} They usually are not encapsulated⁶⁰ but are well-circumscribed,^{59,60} solid, nodular lesions.⁵⁰ They often appear hyperechoic and may have cystic areas within them.^{8,40} Some are heterogeneous and may contain minute, speckled calcifications⁵⁰ or a central, stellate scar. Hamartomas range in size from a few millimeters to centimeters, with a median size of 5 cm.^{55,61}

Almost half of children with splenic hamartomas are symptomatic at presentation.⁵⁹ Children may present with splenomegaly, recurrent infections, periodic low-grade fever with night sweats, growth retardation, or hematologic abnormalities.^{59,60,62}

Nuclear scintigraphy may demonstrate splenomegaly without a shift in radionuclide uptake. The cross-sectional imaging appearance and degree of contrast enhancement vary.⁵⁰ CT may demonstrate splenomegaly⁶² with or without a contour abnormality.⁵⁵ On MRI, splenic hamartomas are often isointense with normal spleen on T1-weighted images and have variable signal intensity on T2-weighted images.^{8,62} There is diffuse heterogeneous early enhancement after administration of contrast material⁵⁵ and more uniform, prolonged enhancement on

delayed images, except in cystic areas or central scar.⁸ MR characteristics of the mass, combined with uptake of ^{99m}Tc-sulfur colloid, are most suggestive of a benign hamartoma.⁶² Splenic hamartomas have been reported in association with tuberosus sclerosis.^{40,63}

Malignant Lesions

LYMPHOMA

Lymphoma is the most common pediatric splenic solid malignant neoplasm.⁴⁰ Metastatic disease, even in the case of lymphoma, is more common than primary splenic malignant disease.⁸ Approximately one third of patients with lymphoma have splenic involvement.⁴² Splenic involvement in lymphoma can be focal or diffuse. Focal lesions may be miliary, small or large, and single or multiple.^{7,8,42} Diffuse involvement may mimic idiopathic splenomegaly without a discrete lesion. Approximately one third of lymphoma patients have splenomegaly; however, splenomegaly in the absence of splenic lymphoma can occur in children with lymphoma.³

Focal lesions on ultrasound are typically hypoechoic relative to the normal spleen^{40,41,64} and in some cases may resemble cysts.⁵⁶ Focal lymphomatous lesions are typically low density and nonenhancing on CT examination (Fig. 122-12).⁴¹ Central areas of old hemorrhage, necrosis, or abscess may be present.⁴¹

Lesions are often isointense to hypointense to muscle on T1-weighted images and isointense to hyperintense on T2-weighted images. With dynamic contrast enhancement, certain occult lesions may stand out as hypointense areas in contrast to the enhancing normal spleen.^{7,53} Diffuse infiltration of the spleen with lymphoma may not be detectable on T1- or T2-weighted images,⁴¹ and imaging with ¹⁸F-fluorodeoxyglucose

positron emission tomography (¹⁸F-FDG PET) may help identify diffuse splenic involvement.⁴⁰

In a review of 154 children with Hodgkin's lymphoma who underwent splenectomy for staging laparotomy, the two most important clinical predictors of splenic involvement at the time of surgery were fine to coarse surface nodulation of the spleen and lymph node involvement at the splenic hilum and pancreatic tail.⁶⁵ Seventy-one percent of children with enlarged lymph nodes at the splenic hilum or pancreatic tail had pathologically proven splenic involvement.⁶⁵

LEUKEMIA

The spleen often harbors leukemic cells in children. Sonographic findings at diagnosis usually include splenomegaly with hypoechoic echotexture. Unlike in lymphoma, focal masses are not typical. Hilar or retroperitoneal lymphadenopathy may also be present. After successful chemotherapy, the spleen decreases in size, and echotexture normalizes.³ Despite marked splenomegaly due to leukemic infiltration, the spleen usually maintains a normal, homogeneous attenuation value on CT examination.¹³

METASTATIC DISEASE

Metastatic disease to the spleen is uncommon⁵³ but is the most common splenic malignant disease. Splenic metastases are often microscopic and may not be evident by imaging or gross inspection.¹³ Metastatic lesions can have cystic-appearing areas of hemorrhage or necrosis and can become secondarily infected.⁴¹

Trauma

BLUNT TRAUMA

The spleen is the most commonly injured abdominal organ in children by blunt abdominal trauma, and most of these lesions are managed nonoperatively.⁶⁶⁻⁶⁹ In a meta-analysis of 26 cohort studies, evaluating 1083 children with blunt splenic injury and nonoperative management, 85% of the children had follow-up imaging and 15% did not. None of the children had delayed (after discharge from the hospital) splenic rupture, and there were no deaths.⁷⁰ Injuries are graded by the organ injury scale of the American Association for the Surgery of Trauma for CT imaging.⁷¹ The hemodynamic state and clinical status of the child are the major determinants of whether surgical treatment is necessary.^{2,66,67,72}

Ultrasound is less sensitive than CT in the diagnosis of splenic injuries. Ultrasound often underestimates the size of the splenic injury,⁷³ possibly because the hemorrhage and injury may acutely be isoechoic to normal spleen tissue.

Active extravasation of intravenous contrast material is manifested as a jet or blush of contrast material swirling into an expanding hematoma or blood pool at the site of splenic injury (Fig. 122-13A).⁷⁴ This finding indicates rapid, active bleeding and may necessitate surgical intervention, particularly in adults.^{66,75} Contrast blush in children with splenic injury is associated with higher grades of splenic injury, but only one of six children with this sign required operative management that included splenectomy and left nephrectomy.⁶⁶ Surgery or embolization (Fig. 122-13B, C) may reduce or eliminate the need for transfusion.⁶⁸

Figure 122-12 Lymphoma. The splenomegaly is associated with multiple low-attenuation lesions that do not significantly enhance. Lymphadenopathy is present in the region of the splenic hilum near the pancreatic tail and anterior to the portal vein (arrows). (Courtesy Lisa Lowe, MD, Children's Mercy Hospital and Clinics, University of Missouri, Kansas City, MO.)

Figure 122-13 Splenic trauma. **A.** Contrast-enhanced CT of 14-year-old boy with a splenic injury after a motor vehicle collision. One month later, the boy had a syncopal episode and was hypotensive. The healing fractured spleen had spontaneously ruptured. Intraperitoneal blood surrounds the liver and the fractured spleen (arrowheads). There is a mixed-attenuation hematoma with a focal concentrated collection of extravasated intravenous contrast material (arrow), indicating active bleeding in the anterior aspect of the spleen. **B.** Selective arteriogram of a splenic end artery demonstrates focal extravasation (arrow). **C.** Coil (arrow) embolization was performed to stop hemorrhage. **D.** Healing spleen has a heterogeneous echotexture. Relatively hypoechoic areas (arrows) are likely to represent an evolving hematoma and necrotic splenic tissue.

If the patient with an isolated splenic or hepatic injury remains hemodynamically stable, repeated imaging is usually not indicated.^{70,72,76} Cyst formation in the area of prior injury is likely to represent resolving hematoma (Fig. 122-13D).⁷⁶ The time for healing, as determined by ultrasound imaging, increases with the severity of the splenic injury.⁷⁶

SPLENOSIS

Splenosis occurs when the splenic capsule is disrupted, by trauma or surgery, allowing intraperitoneal spread of splenic pulp.^{4,77,78} Unlike congenital splenules, the splenic tissue in splenosis may be located anywhere in the peritoneum or may be intrathoracic if the diaphragm is not intact, has a blood supply donated by local tissue, and lacks a capsule.⁷⁸

Splenosis is frequently asymptomatic. However, complications have been reported, including abdominal or pelvic pain, bowel obstruction, splenic implant torsion, relapse of hemolytic disease after splenectomy, and traumatic rupture.^{4,79}

Imaging may demonstrate multiple 1-mm to 5-cm soft tissue masses with an imaging appearance of normal splenic tissue.⁷⁹ They can be located anywhere in the abdominal cavity, most frequently on the small bowel serosa. Splenosis may be mistaken for a disease process such as lymphoma, peritoneal

carcinomatosis, or endometriosis.⁷⁷ Nuclear scintigraphy with ^{99m}Tc-sulfur colloid or denatured red blood cells may confirm the diagnosis of splenosis.^{10,80}

Infections

CANDIDIASIS

Multiple splenic abscesses are usually seen with nonbacterial organisms, most frequently *Candida* infections. Fungal microabscesses are typically seen in children with immunosuppression related to hematologic malignant neoplasms.⁸ These microabscesses may be too small to resolve on imaging.⁸ On ultrasound examination, there are several patterns of hepato-splenic candidiasis. Most commonly, there is a nonspecific pattern of uniformly hypoechoic lesions, although punctate echogenic foci less than 5 mm with variable posterior acoustic shadowing are seen late in the disease and are related to fibrosis with or without calcification (Fig. 122-14).⁸¹ On CT examination, acute microabscesses are typically hypodense to normal spleen and rarely have a central high-density focus, although over time they may become hyperattenuating and may calcify.⁸¹ On MR examination, microabscesses are seen as multiple intermediate signal intensity T1-weighted and hyperintense

Figure 122-14 Candidiasis. For a leukemia patient with a history of *Candida* infection, sonography demonstrates innumerable, punctate, hyperechoic foci (arrows) throughout the spleen, consistent with healed granulomas.

Figure 122-15 Cat-scratch disease. The enlarged spleen has innumerable hypoechoic foci that are consistent with microabscesses. This appearance is not specific for a given organism, and in this 10-year-old girl, it represented infection with *Bartonella henselae*. The lesions may calcify as they heal. (Courtesy Lisa Lowe, MD, Children's Mercy Hospital and Clinics, University of Missouri, Kansas City, MO.)

T2-weighted lesions. They may have peripheral ring enhancement or a target enhancement pattern after administration of gadolinium.⁸

CAT-SCRATCH DISEASE

Cat-scratch disease is caused by the gram-negative bacillus *Bartonella henselae*.⁸² Patients present with unilateral, regional lymphadenitis proximal to the inoculation site as well as constitutional symptoms.^{83,84} In a minority of patients, reticuloendothelial system involvement results in granulomatous or suppurative lesions of the liver and spleen.⁸³ Patients may develop splenomegaly with microabscesses and necrotizing granulomas, which may calcify with healing.⁸³ Multiple hypoechoic splenic lesions are seen on ultrasound (Fig. 122-15).

On CT examination, there are multiple, well-defined, low-attenuation splenic lesions that are better defined after intravenous administration of contrast material.⁸³

The differential diagnosis of the imaging findings includes other granulomatous diseases, such as tuberculosis, histoplasmosis, sarcoidosis, and *Candida* infections, and neoplasms such as lymphoma or other metastatic disease.^{8,83}

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is caused by the Epstein-Barr virus. At least 50% of people with infectious mononucleosis acutely develop splenomegaly⁸⁵ from congestion with numerous, activated T lymphocytes.⁸⁶ The spleen may become markedly enlarged^{87,88} and rarely is complicated by spontaneous splenic rupture.^{87,89} Symptoms of spontaneous rupture include acute left upper quadrant pain and referred left shoulder pain (i.e., Kehr's sign).⁸⁷⁻⁹⁰

Ultrasound examination of spontaneous splenic rupture may demonstrate hypoechoic areas within the spleen, perisplenic and subcapsular fluid collections, and intraperitoneal fluid.

Infarction

Splenic artery branches are end arteries, and splenic vascular occlusion may therefore lead to infarction.^{2,8} Sickle cell hemoglobinopathy is the most common cause of splenic infarcts in pediatric patients. Splenic infiltration by leukemia or lymphoma can also cause infarcts.² Causes of splenic vascular occlusion include embolization, torsion, portal hypertension, collagen-vascular disease, and infiltrative disorders such as Gaucher's disease.² Possible complications of infarctions include fever, abscess or pseudocyst formation, splenic rupture, and hemorrhage.^{2,91}

Splenic infarcts are most commonly peripheral and wedge shaped, although on ultrasound they may appear as one or multiple poorly margined, hypoechoic regions, mimicking abscess or neoplasm.² With time, infarcts become more rounded and better delineated.⁴¹ Eventually, areas of infarction may completely resolve or may leave areas of calcification or small peripheral defects.^{2,91} If the entire spleen is recently infarcted, a hypodense spleen with only capsular enhancement may be seen on contrast-enhanced CT (Fig. 122-16).⁴²

Sickle Cell Disease

The spectrum of hemoglobinopathies in sickle cell disease includes homozygous sickle cell disease (SS), heterozygous sickle cell trait (SC), sickle cell-B⁰ thalassemia, and sickle cell-B⁺ thalassemia.⁹²

SEQUESTRATION

Children with SS disease may develop splenomegaly from sequestration of abnormal cells.² Acute splenic sequestration crisis is an emergent cause of potentially painful splenomegaly in children with SS disease. With sequestration, the splenic outflow is obstructed by sickled red blood cells,⁹³ leading to rapidly increasing spleen size. Hypovolemic shock and death may occur as the spleen traps large volumes of blood.^{94,95}

Figure 122-16 Leukemia and infarction. **A.** Noncontrast CT performed to assess pulmonary infection demonstrates splenomegaly in a teenager with leukemia. Peripherally located, hypoattenuating areas (arrows) may represent areas of infarction, infection, or tumor infiltration. **B.** Contrast-enhanced CT obtained 13 days later to evaluate the acute onset of left upper quadrant pain demonstrates an interval increase in spleen size. The spleen has a large area of decreased attenuation and relative lack of enhancement. The capsule (arrowheads) and some peripheral parenchyma (arrows) have normal attenuation and enhancement. Splenectomy confirmed splenic infarction.

Affected children are typically younger than 2 years,² although episodic sequestration in the spleen may occur up to the age of 5 years with SS disease^{93,94} and in older children and adolescents with SC disease.⁹³

Sonography reveals an enlarged and heterogeneous spleen with hypoechoic areas internally. Doppler examination shows patency of the main splenic vein and intrasplenic veins.⁹⁶

Contrast-enhanced CT may demonstrate multiple peripheral, nonenhancing, low-attenuation areas or large, diffuse nonenhancing low-attenuation areas. The spleen may return to a normal, homogeneous appearance, although splenomegaly may persist.⁹³

NORMAL ISLANDS OF SPLENIC TISSUE

Over time, the spleen of children with sickle cell disease becomes increasingly heterogeneous. On ultrasound examination, hyperechoic areas are thought to represent areas of prior infarction, and hypoechoic areas are thought to represent areas of normal splenic tissue.

On MR, islands of normal splenic tissue retain normal signal, whereas areas of decreased signal intensity on T1- and T2-weighted images are seen with hemosiderin deposition^{53,97} (Fig. 122-17) and calcification.^{97,98} T1-weighted, gradient-echo recalled in-phase and opposed-phase sequences can further accentuate the presence of iron because of the T2* effects.⁹⁹ Normal islands of splenic tissue do not significantly change in signal intensity between in-phase and opposed-phase sequences (Fig. 122-18). However, because of the continued decay of the transverse magnetization imposed by the iron's paramagnetic effects, there is appreciable signal loss on the second phase of the double gradient-echo technique in tissue with abnormal iron deposition.⁹⁹

The spleen may eventually develop dense calcifications, which may accumulate radiotracer during bone scintigraphy. Photopenic areas may correlate with the normal residual islands of functioning splenic tissue.¹⁰⁰ These normal islands accumulate ^{99m}Tc-sulfur colloid, indicating functioning splenic tissue, and have normal signal intensity on T1- and T2-weighted images, which can help differentiate these normal

Figure 122-17 Sickle cell disease. The half-Fourier acquisition single-shot turbo spin-echo (HASTE) image shows low signal intensity of the renal cortex (arrows) and the spleen (arrowheads), indicating iron deposition.

islands from pathologic processes such as abscess, infarct, or neoplasm.^{98,100}

FUNCTIONAL ASPLENIA

Recurrent vaso-occlusive events may lead to a complete functional loss of the spleen's reticuloendothelial cells by the age of 7 years.¹⁰¹ Autosplenectomy and splenic atrophy are seen most often in the hemoglobin SS patients. Nevertheless, the spleen is sonographically visible in 64% of children 9 to 17 years old with SS disease, compared with 96% to 100% sonographic visibility of the spleen in other sickle cell subtypes.⁹²

It has been reported that splenic function has returned after bone marrow transplantation in children with sickle cell disease and functional asplenia, with return of splenic uptake documented on nuclear scintigraphy.¹⁰¹

Figure 122-18 Normal island of splenic tissue (arrows) among siderotic nodules. **A.** Opposed-phase image (TE = 2.4 ms) of a double gradient-echo technique is characterized by the fat-water cancellation (i.e., chemical shift) artifact. **B.** The in-phase image (TE = 5.0 ms) is acquired last. The siderotic nodules have a pronounced decrease in signal intensity relative to their signal on the opposed-phase image. The liver and the normal splenic tissues (arrows) do not contain abnormal amounts of iron and do not demonstrate a significant change in signal intensity between phases.

Figure 122-19 Peliosis hepatis. In the T2-weighted MR image of a surgically resected spleen with peliosis, the signal intensity of the innumerable, subcentimeter, blood-filled spaces is extremely variable.

Peliosis

Peliosis hepatis is characterized by multiple irregular cystic blood-filled spaces located within the liver and occasionally in the spleen or bone marrow. The pathogenesis of peliosis is uncertain,^{102,103} although it has been described in patients with tuberculosis, anabolic steroid use, oral contraceptive use, and human immunodeficiency virus infection.^{8,104,105}

On CT examination, peliosis is often characterized by subcentimeter lesions with variable attenuation; these lesions may resemble microabscesses.¹⁰⁵ The MR signal intensity tends to follow that of blood products, and the T1- and T2-weighted MR signal intensities are variable (Fig. 122-19).¹⁰⁵

Gaucher's Disease

Gaucher's disease is a lysosomal storage disorder caused by deficiency of the enzyme glucocerebrosidase.¹⁰⁶ Glucocerebroside accumulation within the reticuloendothelial system results in hepatosplenomegaly and bone marrow

infiltration.^{6,107,108} Splenomegaly can be marked, with symptoms due to mass effect on adjacent organs.^{107,108} Approximately 30% of patients with Gaucher's disease have numerous splenic nodules,¹⁰⁸ secondary to focal collections of the Gaucher cells and dilated, blood-filled sinusoids. The nodules typically are less than 2.5 cm in diameter.¹⁰⁸

On sonography, the multiple Gaucher nodules can be hypoechoic or hyperechoic within the same patient.¹⁰⁷ On CT, the nodules are hypodense and nonenhancing. On MRI, the nodules are slightly hypointense,¹⁰⁷ isointense, or, least often, hyperintense¹⁰⁸ on T1-weighted images and predominantly hypointense on T2-weighted images.¹⁰⁷ Gaucher nodules have also been described as being hyperintense, target-like (with central hyperintensity), or heterogeneous on T2-weighted images.¹⁰⁷ There may be associated areas of splenic infarction in 33% of patients, particularly in those individuals with larger spleens.¹⁰⁸

Histiocytic Syndromes

Histiocytic syndromes in children are divided into three categories: Langerhans cell histiocytosis; histiocytosis of mononuclear phagocytes other than Langerhans cells, including hemophagocytic lymphohistiocytosis (HLH); and malignant forms, including acute monocytic leukemia and malignant histiocytosis.¹⁰⁹

Langerhans cell histiocytosis is a proliferation of bone marrow-derived histiocytes in aggregates with mature eosinophils.¹¹⁰ Disease may be local or systemic. Splenomegaly with multiple, round, hypoechoic lesions of various sizes that resolve with systemic therapy has been described.¹¹¹

HLH is characterized by uncontrolled activation of the cellular immune system. Clinical criteria include fever, splenomegaly, pancytopenia, hypertriglyceridemia, and hypofibrinogenemia. The three primary sonographic findings in children with HLH are nonspecific and include dramatically striated gallbladder wall thickening of 5 to 7.5 mm; hyperechogenicity of the periportal region, thickened to 6 to 9 mm anterior to the portal vein; and porta hepatis lymphadenopathy.¹⁰⁹ Nodes are less often seen in the splenic hilum, and there is no biliary dilation. Splenomegaly occurs with or without portal hypertension. Half of children have anechoic peritoneal fluid. Because the findings are nonspecific and are seen in children with hepatitis, HLH can be considered if serologic test results for hepatitis are negative.¹⁰⁹

CHAPTER OUTLINE

Embryology

Defects of the Anterior Abdominal Wall

Pentalogy of Cantrell

Omphalocele

Gastroschisis

Exstrophy of the Bladder

Prune-Belly Syndrome

Peritoneum

Peritonitis

Mesenteric and Omental Cysts

Lymphadenopathy and Neoplasms of the Mesentery and Peritoneum

Embryology

At the end of the third week of gestation, the embryo, a relatively flat disk, begins to form a tube by means of four folds. These include one cephalic, one caudal, and two lateral folds, which combine to form the anterior abdominal wall at the region of the umbilicus. Failure of these folds to completely unite may result in defects of the anterior abdominal wall. The type of defect created depends on which of the folds has failed to fuse.

In the developing embryo, the midgut, the portion of bowel from the insertion of the bile duct to the splenic flexure of the colon, rapidly elongates at approximately the fifth to sixth week of gestation, and the abdominal cavity transiently becomes too small to accommodate this bowel. This results in physiologic herniation of bowel into the extraembryonic celom in the umbilical cord. These herniated loops of bowel return to the abdomen at approximately the 10th week of gestation. During this time, the bowel undergoes a 270-degree counterclockwise rotation. The failure of the bowel to return to the abdominal cavity results in an omphalocele. Gastroschisis occurs when herniation of abdominal viscera occurs through a defect in the anterior abdominal wall, usually to the right of the umbilicus.¹

The increasing use of prenatal ultrasound and routine screening with maternal serum α -fetoprotein has enabled earlier diagnosis of defects of the anterior abdominal wall, including pentalogy of Cantrell, omphalocele, gastroschisis, and bladder exstrophy. Although effort has been made to find a common cause for these abdominal wall defects, they seem to be disparate entities.² Overall, the prognosis for these conditions tends to depend on associated congenital anomalies.

Defects of the Anterior Abdominal Wall

PENTALOGY OF CANTRELL

Pentalogy of Cantrell is composed of two major abnormalities—ectopia cordis and a midline thoracoabdominal wall defect—associated with abnormalities of the tissues between these two areas and with defects of the lower sternum, diaphragmatic pericardium, and anterior diaphragm. Less severe cases have been described, which are considered to be incomplete forms. The cause is unclear, but there may be a genetic component. Numerous other abnormalities are associated with pentalogy of Cantrell, including cleft lip and palate³ and limb anomalies.⁴

Clinically, patients generally present with dyspnea and cyanosis. These newborns have an anterior abdominal wall defect, usually an omphalocele, and a structural heart defect, such as atrial septal defect, ventricular septal defect, or tetralogy of Fallot. The anterior abdominal wall defect, paired with the short or cleft sternum, gives the appearance of a high epigastrium filled by the heart.⁴

Diagnosis of pentalogy of Cantrell is usually made by prenatal ultrasound, when findings of omphalocele, ectopia cordis, and congenital heart disease are confirmed. Postnatally, chest radiographs demonstrate abnormal positioning of the heart, usually with dextrorotation. Thoracic abnormalities may also be evident, including pulmonary hypoplasia and rib anomalies.⁴ Computed tomography (CT) can be useful in preoperative evaluation of the thoracic cavity before repair of ectopia cordis.³ CT angiography and magnetic resonance imaging (MRI) can define cardiovascular anatomy, the degree of diaphragmatic deficiency, and the degree of transdiaphragmatic herniation of the bowel or liver.⁵

Treatment of pentalogy of Cantrell involves closure of the thoracoabdominal wall defect, but success with corrective surgery has been limited. Postoperative complications include increased intrathoracic and intra-abdominal pressures, which can result in respiratory and cardiovascular compromise.⁴ The prognosis depends on the severity of the cardiac anomalies and on the severity of any other associated abnormalities.³

OMPHALOCELE

An omphalocele is herniation of abdominal viscera into the intact umbilical cord, with a membranous covering over the eviscerated organs unless there has been membrane rupture (Fig. 123-1). The spectrum of severity ranges from a small umbilical hernia to a large defect, resulting in evisceration of all abdominal organs.⁶ The incidence of omphalocele is 1 case in 4000 to 7000 live births.² Although an omphalocele can be an

Figure 123-1 Giant omphalocele. isolated abnormality, associated anomalies are more common with an omphalocele than with gastroschisis.⁷ Associated genetic abnormalities are seen in up to 54% of patients; trisomy 18 is most common, but trisomy 13, Beckwith-Wiedemann syndrome, and rarely uniparental disomy (i.e., inheritance of both copies of a chromosome pair from one parent and none from the other) also occur. Studies suggest that associated chromosomal abnormalities are more likely in patients with a small omphalocele that does not include herniated liver.^{2,7} Visceral abnormalities are seen in up to 70%, including neural tube defects and cardiac, renal, facial, and skeletal abnormalities and pentalogy of Cantrell.^{2,7} Gastrointestinal anomalies can include imperforate anus, colonic atresia, and Hirschsprung's disease.

Physiologic herniation of bowel is normally seen between the 8th and 12th weeks of gestation; omphalocele cannot be reliably diagnosed until after this period. Omphalocele usually is diagnosed on prenatal ultrasound; patients with omphalocele demonstrate abdominal viscera within a mass at the umbilical cord insertion site⁶ with a covering membrane (Fig. 123-2). The abdominal wall defect of an omphalocele tends to be large.⁷ The herniated viscera usually include liver with various amounts of bowel.⁶ When the omphalocele contains herniated liver and biliary structures, it is referred to as a giant omphalocele (Fig. 123-3).² Ascites can be seen within the abdomen

or omphalocele, and polyhydramnios may be present.⁶ Prenatal diagnosis should also include a thorough search for associated anomalies.⁷ Fetal MRI is increasingly performed in patients with omphalocele to characterize the size and location of the anterior wall defect, to characterize the sac and its contents, and to identify associated anomalies (see Fig. 123-3).⁸ In addition, fetal MRI can be used to calculate lung volumes in patients with giant omphalocele to predict the degree of pulmonary hypoplasia, which is predictive of postnatal morbidity.⁹ Postnatal imaging of infants with omphalocele is generally reserved for identification of associated anomalies and should include echocardiography and renal ultrasound.

Studies of the route of delivery for infants with omphalocele have demonstrated no significant improvement in outcome with cesarean delivery compared with vaginal delivery. Cesarean delivery usually is reserved for patients with obstetric indications. Exceptions are patients who have a giant omphalocele, who are at increased risk of fatal hemorrhage from liver injury.²

Unlike in gastroschisis, the herniated bowel and liver in an omphalocele are morphologically and functionally normal.⁷ The membrane that covers the herniated viscera in an omphalocele decreases fluid loss and protects against the metabolic abnormalities commonly seen in patients with gastroschisis.²

Figure 123-3 Omphalocele. Sagittal balanced gradient-echo MR sequence in a 24-week-gestational-age fetus with a giant omphalocele. There is a large anterior abdominal wall defect (white solid arrows) with herniation of a large portion of the liver (arrowheads) and loops of small bowel (dashed arrow). The covering membrane of the omphalocele is clearly seen (open arrows), and a portion of the umbilical cord is seen attaching to the apex of the sac (black arrow).

The treatment of omphalocele is dictated by the presence of comorbidities (cardiovascular compromise, pulmonary insufficiency), the coexisting congenital syndromes or anomalies, and the size of the defect. Surgical options include primary closure for smaller defects and delayed closure, by the “paint and wait” technique, allowing time for the patient to grow enough to accommodate larger omphaloceles (see Fig. 123-1).¹⁰ Functionally, patients with omphalocele are typically spared the problems of bowel motility associated with gastroschisis. The protective covering membrane over the omphalocele affords a protective barrier to amniotic fluid exposure. The prognosis of patients with omphalocele predominantly depends on associated chromosomal or structural anomalies.^{2,7} Infants with an omphalocele and a cardiac anomaly have a mortality rate approaching 80%.² Prognosis is poorer when the covering membrane has ruptured because these patients tend to have significantly smaller birth weight than those with an intact membrane, regardless of omphalocele size. Patients with giant omphaloceles also tend to have pulmonary hypoplasia, which can complicate primary repair.^{6,11}

GASTROSCHISIS

Gastroschisis refers to herniation of abdominal viscera, usually the small and large bowel, through a defect in the anterior abdominal wall, typically to the right of the umbilicus. The umbilical cord insertion is intact, and there is no membrane covering the eviscerated organs (Fig. 123-4).² These bowel loops are subsequently exposed to amniotic fluid in utero.¹²

The incidence of gastroschisis is 1 case in 10,000 live births,² but epidemiologic studies from the United States, Europe, and Japan have found increasing rates of gastroschisis, by as much as 10-fold, during the past decade. This is not thought to represent improved detection or reporting because the incidence of omphalocele has remained stable during the same period,

Figure 123-4 Gastroschisis. **A.** Frontal radiograph of the abdomen in a newborn with gastroschisis on the first day of life. There are multiple fluid-filled loops of bowel outside of the abdomen (arrows) that do not contain a covering. **B.** Frontal radiograph of the abdomen in the same patient after silo placement. The bowel loops (arrows) are now contained within the silo covering. The spring within the base of the silo is indicated by arrowheads.

Figure 123-5 Gastroschisis. **A.** The prenatal transverse ultrasound image demonstrates the bowel (arrows) herniating through an anterior abdominal wall defect to the right of the umbilical cord insertion (arrowhead). **B.** The sagittal image demonstrates eviscerated bowel floating loosely in amniotic fluid without a membranous covering (arrows). L, Lower extremity; P, placenta; S, spine.

and the rate at which the incidence has increased suggests environmental risk factors rather than genetic ones.¹³⁻¹⁵ Although reports of familial gastroschisis suggest an inherited propensity, numerous studies have suggested that teratogens play a role. Gastroschisis is more likely to occur in young mothers who are heavy smokers, use alcohol during pregnancy, have poor nutrition during pregnancy, or use over-the-counter medications with vasoactive properties (e.g., acetaminophen, aspirin, pseudoephedrine, phenylpropanolamine, ephedrine, methylenedioxymethamphetamine [ecstasy]) early in pregnancy. Clusters of infants with this defect have also been described near toxic waste sites.^{2,15}

Unlike omphalocele, gastroschisis tends not to be associated with chromosomal abnormalities. Up to 31% of male patients with gastroschisis have cryptorchidism, and the testicles may be part of the herniated viscera.² Up to 25% of patients with gastroschisis have intestinal atresia or stenosis or other bowel complications. Other than bowel atresias and cryptorchidism, associated anomalies are rare.¹⁵

The cause of intestinal atresia with gastroschisis is unclear, with theories suggesting a common vascular insult causing the gastroschisis and atresia rather than bowel ischemia from constriction by the defect in the anterior abdominal wall.^{2,7} In addition to atresia, the herniated bowel in patients with gastroschisis is usually damaged, with bowel shortening, thickening, and development of a fibrous covering. Most patients have problems with poor bowel motility and absorptive function long after surgical correction of the defect.⁷ Studies have suggested that the causes include exposure to amniotic fluid, constriction-induced injury at the defect, and altered gene expression within enterocytes.^{6,12} The bowel injury that occurs in utero seems to occur late in pregnancy, with findings of progressive bowel dilation and thickening.⁷ Asymmetric bowel wall dilation, with or without meconium peritonitis, suggests bowel atresia.^{6,12} Not all bowel injury occurs in utero; improved prognosis has been described for early repair or silo application, suggesting that some damage may occur postnatally.⁷

The diagnosis of gastroschisis is typically made on prenatal ultrasound, and maternal screening demonstrates elevated serum levels of α -fetoprotein.^{7,12} The diagnosis of gastroschisis can be made as early as 12 weeks of gestation⁷ by ultrasonographic identification of herniated viscera without a covering membrane in the presence of a normal umbilical cord insertion

(Fig. 123-5). The abdominal wall defect is usually small, most often less than 4 cm in diameter. In addition to bowel, organs that can herniate include liver, stomach, testes, and fallopian tubes.⁶

Prenatal diagnosis enables early diagnosis of other abnormalities and allows decisions to be made about the location and timing of delivery, optimizing postnatal care. As with omphalocele, studies have failed to show improved survival or better outcomes for infants with gastroschisis delivered by cesarean section compared with vaginal delivery, with the exception of cases with eviscerated liver.¹² Infants delivered at medical centers with postnatal and surgical experience in the care of gastroschisis have improved outcome compared with patients delivered elsewhere.⁶

Treatment of gastroschisis involves the return of the herniated organs to the abdominal cavity with primary closure, if possible. This tends to be more urgent with gastroschisis than with omphalocele because the lack of a covering membrane results in increased fluid loss. If the abdominal cavity is too small to tolerate a primary repair because of size, a silo repair may be necessary, with the gradual return of the eviscerated organs to the abdominal cavity during several days (see Fig. 123-4). One risk of closure includes increased intra-abdominal pressures that can cause vascular and respiratory compromise,² urethral obstruction, and bowel ischemia.⁶ In cases of cryptorchidism, the testicles are usually returned to the abdominal cavity at the time of repair of the abdominal wall defect, and most eventually descend to the normal scrotal position.²

The prognosis for patients with gastroschisis depends on the presence of small bowel atresia or stenosis and on the condition of the herniated bowel.^{7,12} Postnatal imaging may be requested to detect small bowel strictures or areas of perforation, both of which are seen in complex gastroschisis and may not be predicted by prenatal imaging (Fig. 123-6).¹⁶ Although the cause of bowel injury is unclear, it affects outcome by leading to intrauterine growth retardation, amniotic fluid abnormalities, and preterm labor.⁷ Postnatally, the bowel injury results in poor weight gain, decreased bowel motility, and feeding intolerance.² Return of bowel motility is slow, regardless of the presence or absence of bowel atresia or stenosis.¹²

Mortality of patients with gastroschisis is commonly related to short gut, which can be congenital or can result from volvulus

Figure 123-6 Complicated gastroschisis. Fluoroscopic image after injection of water-soluble contrast material through a jejunostomy tube. There is irregularity of jejunal loops (white arrows) and extraluminal extravasation of contrast material and pooling of contrast material in the silo in at least two separate areas (black arrows).

or necrotizing enterocolitis.¹⁷ Mortality can also be tied to liver disease from prolonged parenteral nutrition, particularly in patients with bowel atresia.²

EXSTROPHY OF THE BLADDER

With an incidence of approximately 2 cases per 100,000 live births, bladder exstrophy is a rare congenital anomaly. Epidemiologic studies suggest an equal male-to-female ratio and a higher incidence among white patients compared with non-white patients (e.g., blacks, Hispanics, Asians).¹⁸

Bladder exstrophy results from a failure of closure of the anterior abdominal wall at the ventral end of the cloacal membrane.⁷ This defect produces anterior herniation of the bladder, bladder neck, and urethra.¹⁹ There is also malformation of the external genitalia, including epispadias and a small phallus in male patients and an open urethral plate and labial separation in female patients.²⁰ Other associated anomalies can include cleft palate, neural tube defects, cardiovascular and musculoskeletal abnormalities, and preterm birth.¹⁸

Because the findings of bladder exstrophy can be subtle, the diagnosis is often not made on the basis of routine screening prenatal ultrasound.²¹ Persistent nonvisualization of the bladder in combination with normal-appearing kidneys and a normal volume of amniotic fluid should raise the suspicion of bladder exstrophy. Care must be taken to avoid mistaking a completely empty bladder for an absent one because the fetal bladder normally fills and empties every 50 to 155 minutes. A soft tissue mass that can be seen in the lower abdominal wall represents the exstrophied bladder. Additional findings of bladder exstrophy include a low insertion of the umbilical cord, a small phallus and epispadias in male patients, and splaying of the iliac crests.^{20,22}

Figure 123-7 Prune-belly syndrome. Photograph of newborn infant with prune-belly syndrome shows the typical appearance, with redundant, wrinkled skin covering a protuberant abdomen that lacks normal musculature.

Bladder exstrophy repair usually is staged. The initial stage includes closure of the bladder, posterior urethra, and anterior abdominal wall, possibly with pelvic osteotomy, depending on the amount of pubic diastasis present at birth. Subsequent stages include epispadias repair and bladder neck reconstruction.²³ Findings suggest greater success when bladder closure is performed early.²⁴

As with other defects of the anterior abdominal wall, there has been no evidence to suggest that cesarean section improves outcome, but delivery at a hospital with experience in surgical care of bladder exstrophy is recommended because of resultant improved outcomes.^{7,23} There is no significant perinatal mortality associated with bladder exstrophy; however, there can be significant long-term morbidity, particularly urinary, with approximately 70% of patients requiring major reconstruction to achieve continence. Male and female patients experience decreased fertility.²¹

Prune-Belly Syndrome

Prune-belly syndrome, also known as Eagle-Barrett syndrome or triad syndrome,²⁵ is composed of abdominal wall muscle laxity, bilateral undescended testes, and urologic abnormalities.^{26,27} *Pseudo-prune-belly syndrome* refers to patients in whom not all of the classic triad is present.²⁸ The term *prune belly* is derived from the wrinkled appearance of the skin overlying the anterior abdominal wall due to the muscle laxity (Fig. 123-7).²⁵

The cause of prune-belly syndrome is unknown. Theories include a fetal insult resulting in poor abdominal muscle development and muscle atrophy from chronic intrauterine abdominal distention (i.e., chronic bladder distention from posterior urethral valves).^{25,28} There also seems to be a familial form of the disease with an unclear mode of transmission.²⁷ Prune-belly syndrome occurs almost exclusively in boys,²⁵ although in the familial form it is slightly more common in girls (28% of patients, compared with 5% in the nonfamilial form).²⁷

Structural abnormalities of the genitourinary tract include various degrees of renal dysplasia. The ureters are dilated and tortuous bilaterally. The bladder is capacious, often with a urachal remnant, including a urachal diverticulum or fistula. The patient may have urethral abnormalities, including urethral hypoplasia or atresia.^{26,28}

Other anomalies associated with prune-belly syndrome involve the musculoskeletal, cardiovascular, and gastrointestinal systems.²⁵ Gastrointestinal anomalies include malrotation, imperforate anus, and Hirschsprung's disease.²⁸ These patients are prone to pulmonary infections and tend to develop scoliosis due to abdominal muscle weakness.²⁶

On sonographic evaluation, patients with prune-belly syndrome demonstrate dilated, tortuous ureters and bilateral hydronephrosis. The kidneys may be dysmorphic or demonstrate cystic changes.²⁵ The bladder tends to be enlarged but does not appear trabeculated.²⁵ On voiding cystourethrography, patients are found to have a large, elongated bladder, often with a urachal diverticulum or fistula. Eighty-five percent of these patients have vesicoureteral reflux, which often is bilateral, into dilated tortuous ureters (Fig. 123-8). On voiding, the prostatic urethra is generally dilated, with tapering into the membranous urethra. Contrast material can also reflux into the prostatic utricle.²⁵ Patients tend to have large postvoid residual volumes of the bladder.

With regard to prognosis, there seems to be two groups of patients. The first group includes patients with significant genitourinary abnormalities, particularly chronic urethral obstruction, and pulmonary hypoplasia. They tend to be stillborn or die shortly after birth.²⁶ The second group tends to have adequate renal function, although anatomic and functional abnormalities may be present, including dilation of the urinary tract and vesicoureteral reflux. The prognosis for the second group depends on the occurrence of obstruction, sepsis, and chronic renal failure from recurrent urinary tract infections. Many die within the first 2 years of life.^{25,26} Dilation of the urinary tract does not correlate with renal function.²⁹

Peritoneum

PERITONITIS

Bacterial peritonitis in the pediatric population is commonly a result of bowel perforation in association with appendicitis, although other causes include infection from peritoneal dialysis catheters and ventriculoperitoneal shunts (Fig. 123-9).³⁰ Primary bacterial peritonitis, an inflammatory condition of the abdomen of unknown origin, is a rare entity in the pediatric population. Clinical presentation may be similar to acute appendicitis with diffuse abdominal pain, fever, and leukocytosis. Primary bacterial peritonitis is most commonly seen in patients with an underlying chronic illness, such as chronic renal disease, disseminated lupus, liver disease, or

Figure 123-8 Prune-belly syndrome. Anteroposterior view of the abdomen during voiding cystourethrography demonstrates an enlarged, capacious bladder with reflux into the left ureter (arrows) and into the right renal collecting system, with right pelvocaliectasis (arrowheads).

immunosuppression.^{31,32} Peritoneal cultures typically grow a single strain of bacteria, typically gram-positive cocci, thought to reach the peritoneum by hematogenous, lymphatic, or transmural spread.

Imaging findings of primary bacterial peritonitis include complex ascites (fluid with septations and enhancement of the peritoneum) and omental inflammation, both of which may be out of proportion to any inflammatory changes in bowel. The diagnosis is confirmed with paracentesis and a fluid culture that demonstrates growth of a single bacterial species. Growth of multiple species is more consistent with perforated bowel than with primary bacterial peritonitis.³¹

Mesenteric and Omental Cysts

Omental and mesenteric cystic lesions are most often lymphatic malformations.³³ Lymphatic malformation is the preferred term of lesions that were formerly referred to as lymphangiomas or cystic hygromas.³⁴ These rare intra-abdominal cystic masses have an origin in abnormal lymphatics that lack a normal connection to the central lymphatic system.³⁵ The lesions tend to be multiseptate, mobile, and thin walled.³⁵

Mesenteric lymphatic malformations are most commonly found within the mesentery of the small bowel, but they can occur anywhere along the gastrointestinal tract from the duodenum to the rectum³⁶ or can be attached to the peritoneal lining of the abdominal cavity.³⁷ Within the mesentery, these lesions can extend from the base of the mesentery into the

Figure 123-9 Peritonitis. A 3-year-old boy presenting with diffuse abdominal pain and physical examination findings consistent with peritonitis. Axial contrast-enhanced CT of the abdomen and pelvis revealed peritoneal thickening and enhancement (arrow) with complex ascites (asterisk). Surgery confirmed perforated appendicitis (not shown).

retroperitoneum. Approximately 75% of mesenteric cystic lesions are found in young adults or children older than 10 years.³⁵ Omental cystic lesions are contained within the greater or lesser omentum,³⁶ and they are usually seen in children, with 68% occurring in patients younger than 10 years.³⁸

Although patients with both types of lesions can be asymptomatic at the time of diagnosis, some may present with findings of abdominal distention or a “pulling sensation” in the abdomen.³⁵ Patients may also present with findings of an acute abdomen related to bowel obstruction from volvulus or mass effect, from infection or hemorrhage into the lesion,³⁵ or from the lesion’s undergoing torsion or rupture.³⁸ Rarely, patients may develop respiratory, hepatic, or renal compromise from the mass effect.³⁸ Although the diagnosis of a mesenteric or omental lymphatic malformation usually is made with ultrasound, CT, or MRI, radiographs of the abdomen classically demonstrate a homogeneous, water density mass that displaces bowel loops. These findings are nonspecific, however, and radiographs and fluoroscopic studies can be nondiagnostic.³⁹

Because of its lack of ionizing radiation and ready availability, ultrasound is the initial imaging modality of choice. Ultrasound imaging demonstrates an intra-abdominal cystic mass, usually with thin septations. Internal debris may be seen, consistent with hemorrhage or infection (Fig. 123-10).³⁶ CT imaging demonstrates a large, low-attenuation mass with a very thin or

Figure 123-10 Mesenteric cyst. Transverse ultrasound image of an 8-year-old boy with gradually worsening abdominal pain demonstrates a multiloculated cystic mass in the epigastric region with internal debris. The pancreas could not be visualized on this examination.

Figure 123-11 Mesenteric lymphatic malformation. A 3-year-old boy with a mesenteric lymphatic malformation. Axial postcontrast CT images of the abdomen show a large hypoattenuating mass in the abdomen and pelvis (asterisks) with a few thin septations (arrowhead), which causes anterior displacement of bowel (arrows).

indiscernible wall (Fig. 123-11).⁴⁰ The lesion may be multiseptate and have fine mural calcifications (Fig. 123-11).³⁶ MRI shows signal characteristics similar to lymphatic malformations in other locations, with a mass that is predominantly increased signal intensity on T2-weighted images with low signal intensity septations, decreased signal intensity on precontrast T1 images, and peripheral and septal enhancement after administration of

Figure 123-12 Mesenteric lymphatic malformation. A 4-year-old boy with a mesenteric lymphatic malformation. **A.** Axial T2-weighted fat-suppressed MR image of the pelvis shows a mesenteric mass with increased signal intensity (white arrowheads) and multiple low signal intensity thin septations (black arrowheads). **B.** Axial T1-weighted fat-suppressed MR image of the pelvis shows only thin peripheral and septal enhancement (arrowheads).

Figure 123-13 Mesenteric cyst. Gross image of a mesenteric cyst (arrows) centered in the mesentery of the distal small bowel.

contrast material (Fig. 123-12).⁴¹ CT and MRI can be helpful in demonstrating that this mass does not arise from the kidneys, ovaries, or pancreas.³⁷ Whereas a mesenteric cyst tends to be surrounded by bowel loops or to compress the bowel anteriorly if it arises at the base of the mesentery, an omental cyst tends to compress bowel posteriorly.³⁶

The treatment of mesenteric and omental cysts involves surgical resection to prevent torsion, bleeding, or infection³⁸ and usually results in resolution of symptoms.³⁷ Complete excision is recommended to prevent recurrence (Fig. 123-13).³⁵ More recently, percutaneous image-guided sclerotherapy of abdominal lymphatic malformations with doxycycline has been shown to be a safe and effective primary treatment.⁴²

Lymphadenopathy and Neoplasms of the Mesentery and Peritoneum

In the pediatric population, focal solid masses within the abdominal mesentery may be lymphomas, desmoids, teratomas, and lipomas. When the masses are multiple, they usually represent lymphadenopathy, which in the pediatric population

Figure 123-14 Mesenteric adenitis: ultrasound features.

Sonographic evaluation of a 12-year-old boy with abdominal pain demonstrates lymphadenopathy (arrows) in the right lower quadrant (cursors). The appendix was normal (not shown).

is more likely to be inflammatory or infectious than neoplastic. In the pediatric population, malignant lymphadenopathy is commonly caused by lymphoma, lymphoproliferative disorders, and metastatic disease.⁴⁰

On sonographic evaluation, the standard for mesenteric lymphadenopathy in children has been defined⁴³ as a short-axis diameter greater than 4 mm⁴⁴ and a long-axis diameter greater than 10 mm determined by graded compression sonography (Fig. 123-14). Abdominal lymphadenopathy, however, can be underestimated by ultrasound because of obscuration by bowel gas, a limited field of view, and operator dependence.⁴⁵ CT is a more sensitive imaging modality for the evaluation of abdominal lymph nodes. The pediatric standard for mesenteric lymphadenopathy determined by CT is a short axis greater than 8 mm; studies have shown that this standard would result in a false-positive rate for 5% of children.⁴⁵ The echogenicity of a

node is not sensitive for distinguishing normal nodes from lymphadenopathy.⁴⁶

A common cause of mesenteric lymphadenopathy in the pediatric population is mesenteric adenitis. Mesenteric adenitis is characterized by benign inflammation of mesenteric lymph nodes and is sometimes associated with enteritis.⁴⁰ Patients tend to present with acute, chronic, or recurrent abdominal pain with no evidence of other disease,⁴⁵ and they can have additional findings of nausea, vomiting, diarrhea, right lower quadrant pain and tenderness, fever, and leukocytosis. Mesenteric adenitis can be difficult to differentiate from acute appendicitis because of the similarities in clinical presentation.⁴⁰ Confounding this issue is the fact that enlarged lymph nodes have been described in normal, asymptomatic children in the ileocecal and para-aortic regions.⁴⁶

CT findings of mesenteric adenitis include lymphadenopathy anterior to the right psoas muscle and in the small bowel mesentery. This adenopathy tends to be more widespread than that seen with appendicitis, which tends to be isolated just anterior to the right psoas. Inflammatory changes of the mesentery have also been described.⁴⁰

Infectious or inflammatory lymphadenopathy in the pediatric population may result from tuberculosis, cat-scratch disease, fungal infection, or sarcoidosis.⁴⁰ Although most lymphadenopathy on CT is homogeneous, with attenuation similar to that of muscle, nodes that demonstrate central low attenuation with peripheral enhancement are more consistent with an infectious or inflammatory process than a neoplastic one.⁴⁰ This pattern of enhancement has been described as characteristic of tuberculosis (seen in approximately 60% of cases), but it can be seen in any process associated with central node necrosis. Tuberculosis has also been described as having more marked mesenteric than retroperitoneal lymphadenopathy.⁴⁰

Mesenteric lymphadenopathy is commonly seen in patients with Crohn's disease. Affected lymph nodes can be seen throughout the mesentery, from the root to the periphery, or they can be more focal and found in the right lower quadrant. Associated inflammatory bowel changes are not necessary for adenopathy to be present (Fig. 123-15).⁴⁷ Mesenteric adenopathy can also be seen with sarcoidosis and connective tissue disorders, but it is usually not the only imaging abnormality.⁴⁷

In the pediatric population, malignant lymphadenopathy commonly results from lymphoma, lymphoproliferative disorders, and metastatic disease. In lymphoma, nodes tend to start as small and discrete but can coalesce, forming a soft tissue mass (Fig. 123-16). This nodal mass has a characteristic appearance, growing around and displacing normal vessels and bowel.⁴⁷ On CT, the nodes usually demonstrate soft tissue attenuation with homogeneous enhancement, although peripheral enhancement has been described. Calcified lymph nodes are rare in untreated lymphoma, with a prevalence of less than 1%, but nodes commonly calcify after treatment.⁴⁷

Lymphoma that is manifested with abdominal lymphadenopathy is usually non-Hodgkin's lymphoma, and the adenopathy usually involves the mesentery and the retroperitoneum.⁴⁰ The lymphoproliferative disorders induced by Epstein-Barr virus tend to have extranodal parenchymal involvement rather than lymphadenopathy.^{48,49}

Solid masses of the mesentery are rare in the pediatric population. Desmoid tumors can be seen in patients with a history of Gardner's syndrome or with a history of prior

Figure 123-15 Lymphadenopathy. An 8-year-old girl with Crohn's disease. Coronal reformat image from a contrast-enhanced CT scan of the abdomen and pelvis. There is bowel wall thickening and hyperenhancement of the terminal ileum (solid arrows). Multiple enlarged mesenteric lymph nodes are present in the right lower quadrant (arrowheads). Engorgement of the vasa recta is also noted (dashed arrows).

Figure 123-16 Lymphoma. Transverse CT image of 3-year-old child with lymphoma demonstrates a soft tissue nodal mass along the mesentery (arrows) and para-aortic and aortocaval retroperitoneal lymphadenopathy (arrowheads).

surgery or trauma.⁴⁰ Additional differential considerations for mesenteric masses include a solitary inflammatory or neoplastic lymph node and inflammatory pseudotumor.⁴⁰ Desmoplastic small round cell tumor is a rare malignant tumor that usually is manifested as a dominant mass in the pelvis with multiple peritoneal metastases as well as other metastatic disease at diagnosis (Fig. 123-17).^{50,51} Peritoneal metastases are rare in children but can also be seen with malignant ovarian tumors.

Renal Colic

Conclusions

The term *acute abdomen* defines a clinical syndrome characterized by the sudden onset of severe abdominal pain requiring emergency medical or surgical treatment. A prompt and accurate diagnosis is essential to minimize morbidity and mortality. The differential diagnosis includes an enormous spectrum of infectious, inflammatory, obstructive, and neoplastic disorders ranging from benign self-limited diseases to conditions that require emergency surgery (Fig. 124-1). In a review of approximately 30,000 patients with acute abdomen, Shah observed that 28% of patients had appendicitis, 9.7% had acute cholecystitis, 4.1% had obstruction of the small bowel, 4% had acute gynecologic disease, 2.9% had acute pancreatitis, 2.9% had acute renal colic, 2.5% had perforated peptic ulcer, and 1.5% had diverticulitis. For one third of patients, no cause could be determined.¹

The clinical diagnosis of acute abdomen can be challenging because results of physical examination, clinical presentation, and laboratory examination are often nonspecific and nondiagnostic.²⁻⁵ Sonography has developed a niche in evaluating the gallbladder in all patients and the appendix in children and pregnant women. Magnetic resonance (MR) is being used with increasing frequency in pregnant women. Multidetector computed tomography (MDCT), however, has become the premier technique for triage of most patients with acute abdomen. MDCT has earned this role because it can provide a global perspective of the gut, mesenteries, omenta, peritoneum, retroperitoneum, subperitoneum, and extraperitoneum uninhibited by the presence of bowel gas and fat. MDCT scanning allows thinner contiguous images to be obtained without increasing radiation exposure and without respiratory misregistration. Multiplanar reformatted images can be obtained with virtually isotropic data sets. The rapidity of scanning allows several acquisitions to be obtained during different phases of a single intravenous bolus of contrast material.⁶ The cross-sectional imaging features of the most common abdominal disorders causing the acute abdomen are discussed in this chapter.

Technical Considerations

A variety of MDCT protocols for preparation of the patient and scanning have been created to study the diversity of diseases that can cause acute abdomen. The selection of an imaging technique depends on the most likely diagnosis, clinical setting, and local expertise. The examination should be tailored to each patient. See Chapter 5 for a more complete discussion of abdominal CT protocols.

It is best to obtain a general survey examination that includes the entire abdomen and pelvis. Diagnostic errors will occur if the anatomic coverage is dictated solely by the vagaries of clinical diagnosis. Scans are obtained from the diaphragm to beneath the symphysis pubis. Coronal and sagittal reformatted images are helpful in establishing a diagnosis.³

Intravenous administration of contrast material is helpful in the diagnosis of splanchnic venous thrombosis, bowel ischemia, aneurysms, and active arterial extravasation as well as solid parenchymal organ abnormalities. Inflammatory mural changes in appendicitis, cholecystitis, diverticulitis, Crohn's disease, and infectious enterocolitis are also better depicted with vascular enhancement. Neoplasms, abscesses, and infarcts in the liver, spleen, and kidneys are well portrayed on contrast-enhanced scans. Intravenously administered iodinated contrast material carries the risk of nephrotoxicity and potential reaction to the agent, and it may obscure renal and ureteral stones. However, in most patients, the information provided justifies the risk and extra expense. Between 125 and 150 mL of 60% iodinated

Figure 124-1 Leading causes of acute abdominal pain by quadrants. **A.** Causes of right upper quadrant pain: 1, cystic duct obstruction; 2, cholecystitis; 3, cholangitis, biliary obstruction; 4, duodenitis, duodenal ulcer; 5, gastritis, gastric ulcer; 6, pancreatitis, pancreatic cancer; 7, pyelonephritis, renal infarction, renal or ureteric stone, hydronephrosis; 8, subhepatic appendicitis; 9, pneumonia, pleural effusion, pulmonary embolism; 10, hepatitis, liver abscess, hemorrhage in liver tumor, acute hepatic congestion (right-sided heart failure), Budd-Chiari syndrome, portal vein thrombosis. **B.** Causes of left upper quadrant pain: 1, gastritis, gastric ulcer; 2, pancreatitis, pancreatic cancer; 3, subphrenic abscess; 4, splenic infarction and infection; 5, cardiac causes, including pericarditis, pericardial effusion, myocardial infarction; 6, left lower lobe pneumonia, effusion, pulmonary embolism; 7, hiatal hernia, gastroesophageal reflux disease; 8, pyelonephritis, renal infarction, ureteric stone. **C.** Causes of right lower quadrant pain: 1, appendicitis; 2, mesenteric adenitis, torsion of the greater omentum; 3, Meckel's diverticulum, ileal diverticulitis; 4, Crohn's disease, infectious or ischemic ileitis; 5, diverticulitis of a redundant sigmoid colon; 6, infectious, ischemic, or inflammatory colitis, epiploic appendagitis; 7, renal infection or infarction, ureteric stone; 8, ovarian disease, including cyst rupture, torsion, pelvic inflammatory disease, ectopic pregnancy; 9, infectious and inflammatory cystitis. **D.** Causes of left lower quadrant pain: 1, diverticulitis, epiploic appendagitis; 2, infectious, inflammatory, or ischemic colitis; 3, ovarian disease, including cyst rupture, torsion, pelvic inflammatory disease, ectopic pregnancy; 4, pyelonephritis, renal or ureteric stone; 5, infectious and inflammatory cystitis. (From Dieter B, Modder U: *Diagnostic Imaging of the Acute Abdomen*. Berlin, Springer-Verlag, 1988, p 5.)

contrast material should be injected intravenously at a rate of at least 3 mL/s. Scans are obtained during the portal venous phase with a 60- to 70-second delay. Arterial phase imaging (40-second delay) is useful in patients with suspected hemorrhage, bowel ischemia, and arterial thrombosis. Delayed scans through the kidneys and pelvis can reveal pyelonephritis, renal masses, and bladder disease that might have been overlooked during earlier phases.⁴⁻⁶

When bowel obstruction, intestinal ischemia or infarction, ileus, intestinal infection, or inflammation is suspected, the intrinsic fluid in the gut often serves as an excellent gastrointestinal luminal contrast agent. Positive contrast agents may lead to algorithm undershoot or overshoot and may interfere with assessment of bowel enhancement and viability. No oral contrast agent, water, or a low-contrast agent such as VoLumen may be given in these cases. For suspected kidney or ureteric

stones and ruptured abdominal aortic aneurysms, scans without oral or intravenous administration of contrast material should first be obtained.

For patients with nonspecific symptoms and signs, we prefer to give 800 to 1000 mL of a 2% solution of oral, diluted, water-soluble contrast material at least 1 hour before scanning. Oral contrast material is administered primarily to differentiate bowel loops from abdominal and pelvic masses and abscesses. Oral contrast material may obscure the diagnosis of bowel hemorrhage or ischemia and limit the detection of ureteral stones, appendicoliths, and bile duct stones. Practical difficulties of using oral contrast material include the time it takes to opacify the gut, the randomness of contrast opacification, and the inability of sick patients to consume and to retain sufficient quantities of the agent.

The use of rectal contrast material is advocated by some investigators to optimize the detection of appendicitis, diverticulitis, and epiploic appendagitis. With the patient in the left decubitus position, 400 to 600 mL of a 3% solution of water-soluble contrast agent is administered by gravity through a soft rubber rectal catheter without use of a balloon. The patient is then turned to the supine position for scanning.

An alternative approach to the patient with acute abdomen is to perform CT without oral, intravenous, or rectal administration of contrast media. This technique is fast, is virtually risk free, and causes no patient discomfort. However, these scans are the most difficult to interpret, particularly in patients with little abdominal or pelvic fat.

Appendicitis

Acute appendicitis (Fig. 124-2) is the most common abdominal surgical emergency, affecting approximately 250,000 people annually in the United States.⁷ Although the correct diagnosis can be made in most patients on the basis of the history, physical examination findings, and laboratory test results, the diagnosis is uncertain in 20% to 33% of patients who present with atypical symptoms. The diagnosis is most difficult for infants, young children, elderly patients, and women of reproductive age. In the past, an average negative laparotomy rate

Figure 124-2 Appendicitis. This intraoperative image shows an enlarged and diffusely inflamed appendix.

of 20% was acceptable.⁷ The widespread use of MDCT for patients with suspected appendicitis positively affects patient outcomes and increases the number of laparotomies with positive results. The surgical misdiagnosis rate has been reduced from 20% to 40% without imaging to a current rate of approximately 5% to 10%.^{8,9}

The MDCT, ultrasound, and MR findings of acute appendicitis reflect the extent and severity of inflammation (Fig. 124-3). In mild disease, the appendix appears as a slightly distended (6-15 mm in diameter), fluid-filled structure that shows circumferential symmetric mural thickening (Fig. 124-4). Sometimes, only the tip is inflamed (so-called tip appendicitis). On sonographic examination, periappendiceal inflammation may be encountered, and pain over the appendix may be elicited. The inflamed appendix is often hypervascular on color Doppler ultrasound.^{10,11}

Figure 124-3 Appendicitis: sonographic features. **A.** A dilated, inflamed appendix is visualized along its long axis on this sonogram of the right lower quadrant. **B.** The inflamed appendix, imaged along its transverse axis, shows mural thickening and increased color Doppler flow to the appendiceal wall, attesting to the hyperemia accompanying the inflammation.

Figure 124-4 Appendicitis: CT features. Axial image shows a dilated, fluid- and gas-filled appendix (arrow), with mural thickening and periappendiceal inflammatory changes.

Figure 124-5 Appendiceal abscess. A right lower quadrant abscess (arrows) is identified along the medial aspect of the cecum.

Homogeneous, dense contrast enhancement of the wall is typical on MDCT, but a target sign may be seen on axial images (see Fig. 124-4). Periappendiceal inflammation is manifested as slight haziness of the mesoappendix fat. A calcified appendicolith is more reliably revealed on CT than on plain radiography.¹²⁻²⁰ When it is present, the appendicolith is less well visualized than on CT or ultrasound. With disease progression and perforation, the appendix becomes fragmented, destroyed, and replaced by a phlegmon or abscess (Fig. 124-5). Associated mural thickening of the adjacent distal ileum and cecum may also occur. In patients with these symptoms, the specific diagnosis of appendicitis can be made if an appendicolith is seen in the abscess or phlegmon. If not, the diagnosis of appendicitis can only be suggested within a differential diagnosis that includes cecal diverticulitis, ileal diverticulitis, Meckel's diverticulitis, perforated neoplasm (cecal, appendiceal, or ileal), and Crohn's disease with abscess formation.²⁰⁻³⁰

MR (Fig. 124-6) is becoming increasingly used in pregnant patients with high clinical suspicion of appendicitis. The MR features are similar to those seen on CT. The appendix is distended to a caliber greater than 6 to 7 mm in diameter with surrounding inflammatory change in the mesoappendix. See Chapter 56 for a more complete discussion of appendicitis.

Diverticulitis

Diverticulitis occurs in 10% to 25% of patients with known diverticulosis. It results from a microperforation or, much less commonly, a macroperforation of a diverticulum into the rich pericolic fat in the subperitoneal spaces surrounding the colon. These patients typically present with left lower quadrant pain, fever, and leukocytosis. Clinical misdiagnosis rates range from 34% to 67%.^{31,32} The role of CT for these patients is to confirm the diagnosis, to establish the presence of complications (e.g., abscess), to provide a road map for percutaneous or surgical therapy, and to suggest alternative diagnoses for patients in whom diverticulitis has been excluded.^{33,34}

The CT hallmark of diverticulitis is inflammatory change in the pericolic fat, which is observed in 98% of patients (Fig. 124-7). Minimal haziness of adjacent fat occurs in mild cases. Small

Figure 124-6 Appendicitis: MR features. An inflamed appendix (arrows and arrowhead) characterized by mural thickening, intraluminal fluid, and periappendiceal inflammation is depicted along the lateral aspect of the placenta on this T2-weighted coronal image obtained in a pregnant woman in the third trimester.

Figure 124-7 Diverticulitis of the sigmoid colon: CT findings. Coronal reformatted image shows mural thickening of the junction of the sigmoid and descending colon and a phlegmon (arrows) in the sigmoid mesocolon.

fluid collections, fine linear strands, and extraluminal gas bubbles may also occur. In more severe cases, phlegmon or frank abscess formation can occur. Diverticula are evident in more than 80% of patients, and symmetric mural thickening of more than 4 mm is seen in about 70% of patients. Other typical features include engorgement of the vasa recta and the presence

of fluid in the inferior portion of the combined interfascial plane.³¹⁻³⁴

In some patients, contrast material collects in an arrowhead shape adjacent to the inflamed colonic diverticulum (i.e., arrowhead sign of diverticulitis). The offending inflamed diverticulum may appear as a rounded paracolic outpouching centered in the paracolic inflammation with soft tissue calcium, barium, or air attenuation.³¹⁻³⁴

A perforated carcinoma is the major differential diagnostic consideration for patients with sigmoid diverticulitis. Although the colon wall is usually less than 1 cm thick in acute diverticulitis, in patients with severe muscle hypertrophy, the wall may be 2 to 3 cm thick, simulating carcinoma. CT findings favoring the diagnosis of acute diverticulitis include a tethered or saw-toothed luminal configuration, the presence of fluid in the combined interfascial plane, and engorged vasa recta. An abrupt zone of transition with normal bowel, enlarged local lymph nodes, and mural thickness greater than 1.5 cm favors carcinoma.³¹⁻³⁴

Complications of acute diverticulitis include abscess formation (Fig. 124-8), obstruction of the large and small bowel, secondary inflammation of the appendix, fistula, sinus tracks, and frank intraperitoneal perforation. Right-sided diverticulitis is usually difficult to diagnose clinically. Compared with patients with appendicitis, individuals with right-sided diverticulitis have a more protracted history, milder pain, and a higher point of maximum tenderness, which may clinically simulate acute cholecystitis. A palpable mass is present in up to one third of patients and can mimic an appendiceal or cecal tumor.

The MDCT findings of right-sided diverticulitis consist of focal pericolic inflammatory change, slight mural thickening, and visualization of diverticulum as an outpouching of the right colon at the level of maximum wall thickness. The offending diverticulum contains gas, fluid, contrast material, or calcified material. The normal appendix should be seen. If the

Figure 124-8 Abscess due to sigmoid diverticulitis. A large abscess (A) with an air-fluid level is identified in the sigmoid mesocolon.

appendix is not visualized, appendicitis, epiploic appendagitis, typhlitis, or perforated cecal carcinoma must be considered in the differential diagnosis.³¹⁻³⁴ See Chapter 55 for a more complete discussion of diverticulitis.

Bowel Obstruction

Obstruction of the small intestine and colon accounts for approximately 20% of acute abdominal surgical conditions.³⁵ MDCT has replaced conventional contrast studies because it can more reliably answer several questions. Is obstruction present? What is the level of obstruction? What is the cause of obstruction? What is the severity of obstruction? Is the obstruction simple or a closed loop? Is strangulation or ischemia present?

It is important to differentiate between simple and closed-loop obstruction (Fig. 124-9) because the simple obstruction can be treated conservatively, whereas closed-loop obstruction requires prompt surgical intervention. For patients with bowel obstruction, scans are best obtained without oral contrast material because intraluminal fluid and gas serve as natural contrast agents. Intravenous contrast material is important in assessing intestinal perfusion and ischemia and in delineating the size, configuration, and patency of the mesenteric vessels.³⁶ If oral contrast material is given, a delayed plain abdominal radiograph obtained several hours later can determine if the contrast material has passed into the colon.

The CT hallmark of bowel obstruction is the delineation of a transition zone between dilated and decompressed bowel. Careful inspection of the transition zone and luminal contents often reveals the underlying causes of obstruction. CT is most helpful in patients with internal and external hernias, neoplasms, gallstone ileus, various forms of enteroenteric intussusception, and afferent loop obstruction after a Billroth II operation. If no mass, hernia, intussusception, abscess, or inflammatory thickening is present, adhesion is the most likely diagnosis. The typical adhesion has a beaklike narrowing, and the affected gut may be difficult to view, depending on the orientation of the loop relative to the axial plane. Use of the scroll or leaf function and multiplanar reformations in the coronal and sagittal planes can help establish the correct diagnosis.³⁷⁻⁴⁷

Figure 124-9 Strangulated small bowel obstruction. The intraoperative photograph shows a hemorrhagic-necrotic small bowel due to strangulation caused by a volvulus surrounding an adhesion.

Figure 124-10 Closed-loop small bowel obstruction: CT features. Axial image shows the obstructed ileal loops converging to a central point in this patient with a transmesenteric internal hernia. There is mural thickening of the obstructed loops, hypoenhancement of several of the loops (arrows), and edema of the adjacent small bowel mesentery. Ischemic bowel was found at the time of surgery.

The anterior abdominal wall should be carefully inspected to search for prior surgical scars. The small bowel feces sign is often seen just proximal to the obstruction. If positive oral contrast material is present, it becomes progressively more dilute as it approaches the level of obstruction. Also the degree of small bowel dilation is largest closest to the level of obstruction.

An incarcerated or closed-loop obstruction is manifested as a loop-shaped, fluid-filled structure causing proximal segments to dilate with gas and fluid. The mesenteric vessels have a radial distribution (Fig. 124-10) because they become stretched and converge toward the U- or C-shaped loop. Two adjacent and collapsed round, oval, or triangular segments typically represent the afferent and efferent entry points of the torsion site. The mesenteric vasculature may have an unusual course. When ischemia develops, the bowel wall may thicken and have a target appearance caused by submucosal edema. Enhancement of the involved bowel wall may be poor or delayed. Fluid and hemorrhage may collect in the mesentery, bowel wall, and lumen of the involved segment. The mesentery becomes hazy in appearance, and ascites may develop.³⁷⁻⁴⁷

In patients with high-grade obstruction of the small bowel, CT has a reported sensitivity of 90% to 99%. CT is less accurate in patients with low-grade obstruction. Obstruction of the large bowel (Fig. 124-11) can also be demonstrated by MDCT. See Chapters 46 and 62 for a more complete discussion of bowel obstruction.

Acute Cholecystitis

Acute cholecystitis results from obstruction of the gallbladder and its attendant mural inflammation associated with infection and sometimes necrosis. Most cases are caused by obstructing gallstones in the gallbladder neck or cystic duct. Because acute cholecystitis develops in only 20% of patients with gallstones, many patients with gallstones with right upper quadrant pain have other pathologic conditions responsible for their symptoms.⁴⁸

Only 20% to 30% of patients with right upper quadrant pain have acute cholecystitis. The primary sonographic diagnostic

Figure 124-11 Carcinoma of the sigmoid colon causing large bowel obstruction. The coronal reformatted image shows the obstructing sigmoid mass (curved arrows). The cecum is dilated (double-headed arrow), and there are liver metastases.

Figure 124-12 Acute cholecystitis: sonographic features.

Transverse sonogram of the right upper quadrant shows sludge and shadowing stones within the gallbladder. Mural thickening (arrows) is associated with edema, producing wall stratification. The patient also had a sonographic Murphy sign.

criterion is the sonographic Murphy sign associated with gallstones. Secondary signs of acute cholecystitis include mural thickening (>3 mm) and stratification, a distended or hydropic gallbladder with loss of the normal tapered neck and development of an elliptical or rounded shape, and pericholecystic fluid (Fig. 124-12).^{48,49}

Figure 124-13 Acute cholecystitis: CT features. **A.** Two large stones (curved arrows) are identified within a thick-walled gallbladder. Notice the pericholecystic fluid (straight arrow). **B.** The more cephalad scan, displayed with a narrow window, shows a region of transient hepatic attenuation difference (arrows) surrounding the inflamed gallbladder (GB).

Although sonography is the preferred method for diagnosis of acute cholecystitis, CT is frequently the initial examination because the diagnosis is unclear. The most sensitive CT findings of acute cholecystitis are mural thickening greater than 3 mm (in the setting of a distended gallbladder) and enhancement of the inflamed wall (Fig. 124-13A). Transient, focally increased attenuation of the liver may develop adjacent to the inflamed gallbladder, resulting from hepatic artery hyperemia and early venous drainage (Fig. 124-13B). Less specific signs include pericholecystic fluid, haziness of the pericholecystic fat, and increased attenuation of the gallbladder bile. CT can also depict complications of acute cholecystitis, including perforation and gangrene. Intramural or intraluminal gas is present in emphysematous cholecystitis.^{49,50} See Chapter 77 for a complete discussion of acute cholecystitis.

Choledocholithiasis

Patients with choledocholithiasis typically present with acute right upper quadrant pain, fever, jaundice, and pancreatitis. Thin-collimation scans are needed to optimize the detection of stones on MDCT. A high-density nidus may be visualized in the duct, or alternating low- and high-density rings of mixed cholesterol-calcium stones may be seen. Biliary dilation may be evident proximally. MDCT has a sensitivity of 88%, specificity of 97%, and accuracy of 94% in the detection of choledocholithiasis; however, positive intraluminal and intravascular contrast agents can obscure the detection of peripherally calcified stones.^{49,51,52} MR and MR cholangiopancreatography are the premier means of establishing the diagnosis of choledocholithiasis.

Peptic Ulcer Disease

Patients with peptic ulcer disease often present with nonlocalizing signs and symptoms indistinguishable from those of acute pancreatitis or cholecystitis, and MDCT is normally the first examination ordered. The most common MDCT result is focal mural thickening, which is a nonspecific finding. On occasion, an active ulcer or perforation (Fig. 124-14) is identified, accompanied by inflammatory change of the adjacent fat, mesenteries, and omenta.⁵³

Figure 124-14 Perforated gastric ulcer: CT findings. Extravasated contrast material (arrow) is present in peritoneal spaces of the left upper quadrant.

Pancreatitis

MDCT plays a vital role in the clinical diagnosis (Fig. 124-15), treatment, and staging of patients with acute pancreatitis. MDCT can reveal hemorrhage or necrosis in the pancreas and identify the extension of inflammation in adjacent organs. MDCT findings of acute pancreatitis reflect edema of the gland and surrounding fat and may be normal in up to 28% of mild cases.⁵⁴ The entire gland may become diffusely enlarged and have a shaggy, irregular contour. In mild cases, the peripancreatic fat contains wisps of high attenuation, the vascular margins are cuffed, and the fascial planes are thickened. Mild peripancreatic inflammation may be present around an otherwise normal-appearing gland. Segmental pancreatitis occurs in 10%

to 18% of patients and is usually associated with stone disease. Typically, the gland shows uniform enhancement.⁵⁵

In more advanced cases, intraglandular intravasation of pancreatic fluid leads to the formation of many small, intrapancreatic fluid collections. In necrotizing pancreatitis, the gland becomes enlarged and is often enveloped by high-attenuation exudates. Necrotic parenchyma shows decreased or no enhancement that is sharply demarcated from normally enhancing viable tissue. The body and tail are usually involved; the head is spared because of its rich collateral vascular network. Enhancing islands of viable tissue may be scattered throughout the gland. The poorly defined peripancreatic exudates obliterate the peripancreatic fat, dissect fascial planes, and penetrate through fascial and peritoneal boundaries and ligaments. These collections typically accumulate in the lesser sac, anterior pararenal space, and anterior interfascial space. MDCT is also useful in revealing vascular complications, such as pseudoaneurysms and splenic and portal vein thrombosis.

MDCT can help predict patient outcomes by delineating necrosis. In one study, patients with no evidence of necrosis on

MDCT had 0% mortality and only 6% morbidity rates, whereas patients with large areas of necrosis (50%) had a 75% to 100% morbidity rate and an 11% to 25% mortality rate.⁵⁵ See Chapter 97 for a complete discussion of pancreatitis.

Perforation

Gastrointestinal perforation usually indicates a catastrophic complication of peptic ulcer disease, diverticulitis, severe intestinal inflammation, infarction, trauma, neoplasm, or closed-loop obstruction. MDCT is ideal for evaluating patients with signs of peritonitis, which is often misdiagnosed as another acute lesion. MDCT can detect pneumoperitoneum that may be overlooked on chest or abdominal radiography.⁵⁶⁻⁵⁹ The visualization of extraluminal gas is facilitated by scrolling through the images with lung windows.

Detection of the site of perforation is often difficult but can be assisted by the oral and intravenous administration of contrast material. Loculated fluid and gas (Fig. 124-16), focal mesenteric or omental infiltration, and focal enhancement of the parietal peritoneum can help pinpoint the site of perforation.⁵⁶⁻⁵⁹

Intestinal Ischemia

Vascular insufficiency of the gut is a differential diagnosis for elderly patients with acute abdominal pain or for any patient with a history of coronary artery disease, peripheral vascular disease, arteritis, hypotension, dehydration, or cardiac decompensation. Patients with intestinal ischemia have a broad range of symptoms that make a clinical diagnosis difficult. The major causes of intestinal ischemia include hypoperfusion and arterial or venous occlusion or thrombosis. Typically, the predominance of one factor determines the outcome. CT plays an important role in identifying the early changes of ischemia. Rapid intravenous administration of contrast material (>3 mL/s) is required to optimize vascular opacification and to assess the patency of the superior mesenteric artery and vein.⁶⁰⁻⁶³

The CT features of intestinal ischemia depend on its cause, chronicity, and severity. Mural thickening of the gut is the most common finding, and the wall may have a target or halo appearance caused by submucosal edema. Thickened edematous wall is best appreciated in bowel distended by fluid, air, or contrast

Figure 124-15 Pancreatitis: CT features. An inflammatory fluid collection (arrow) is identified in the left anterior interfascial plane on this axial image.

Figure 124-16 Small bowel perforation due to a chicken bone: CT and gross pathologic findings. **A.** CT shows an air-contrast material level (white arrow) in the small bowel mesentery due to perforation by a chicken bone (black arrow). **B.** Surgical specimen shows the site of the perforation.

Figure 124-17 Colonic infarction with pneumatosis intestinalis and mesenteric venous gas: CT features. Coronal CT image shows pneumatosis (red arrow) in the region of the hepatic flexure of the colon and gas in the superior mesenteric vein (black arrow).

material. This appearance is nonspecific and can be seen in infectious and inflammatory bowel disease. Mesenteric haziness reflects edema and hemorrhage. The presence of focal pneumatosis or thrombus in the celiac, superior mesenteric, and inferior mesenteric arteries and veins permits a specific diagnosis to be made. Air in the bowel wall, mesentery, and portal venous system has grave prognostic implications for patients with ischemic bowel (Fig. 124-17). CT is far more sensitive than radiography in detecting pneumatosis and portal venous gas.⁶⁴⁻⁶⁸

Colonic ischemia usually results from hypoperfusion or hypotension, and mesenteric thrombus is rare. MDCT reveals segmental thickening of the colon with scalloped, irregular margins caused by submucosal edema.⁶⁵ Bowel ischemia is discussed more fully in Chapters 47 and 62.

Abdominal Sepsis

Patients with an abdominal abscess or peritonitis can present with an acute abdomen. Abdominal infections most commonly result from the contiguous spread of bacteria from the gut, biliary tract, or genitourinary system. These infections are typically polymicrobial in nature and include both aerobic and anaerobic organisms. MDCT is the most accurate imaging examination for the diagnosis of intra-abdominal abscesses. Initially, abscesses appear as a mass of soft tissue attenuation caused by the influx of inflammatory cells. With maturation, the abscess undergoes central liquefaction necrosis, and highly vascularized peripheral connective tissue develops. As a result, this lesion has a low-attenuation center with an enhancing rim. Small gas bubbles or air-fluid levels are present in 40% to 50%

Figure 124-18 Epiploic appendagitis. CT shows an elliptical fat density structure (circle), the epiploic appendage, surrounded by increased attenuation in the pericolic fat.

of patients, and they suggest intra-abdominal sepsis. Abscesses tend to be round or oval unless they are adjacent to a solid organ. In these patients, abscesses may develop a lentiform or crescentic configuration. Abscesses also displace surrounding structures, obliterate or thicken adjacent fascial planes, and cause inflammation of the contiguous mesenteric or omental fat.³⁻⁵ See Chapter 72 for a more complete discussion of abdominal abscesses.

Epiploic Appendagitis

This unusual condition occurs when an epiploic appendage of the colon develops inflammation, torsion, or ischemia. Epiploic appendagitis can simulate appendicitis and right- and left-sided diverticulitis clinically and on MDCT scans. The inflamed appendage is manifested as a small, fat-attenuation mass with a hyperattenuating rim that abuts the serosal surface of the colon. At the center of the lesion, a small, round or linear, hyperdense focus may be seen, probably representing vascular thrombosis. Epiploic appendagitis also produces a mass effect, focal thickening of the adjacent bowel, infiltration of the mesenteric fat, and focal thickening of the surrounding peritoneum (Fig. 124-18).⁶⁹⁻⁷¹

MDCT is usually diagnostic. Surgery can be avoided in many cases because epiploic appendagitis is a self-limited disorder. See Chapter 62 for a more complete discussion of epiploic appendagitis.

Omental Torsion and Infarction

Omental torsion or infarction is an uncommon disorder. Portions of the greater omentum undergo torsion or spontaneous

Figure 124-19 Focal torsion-infarction of the greater omentum: CT findings. Axial (A) and coronal (B) images show focal increased attenuation (arrows) of a small portion of omental fat.

Figure 124-20 Mesenteric adenitis: CT features. Coronal reformatted image shows multiple, borderline, enlarged lymph nodes (arrows) in the ileocolic mesentery.

venous thrombosis, or both, which leads to severe abdominal pain associated with exquisite point tenderness. This usually occurs in the right lower quadrant, in which case it clinically simulates acute appendicitis, or in the right upper quadrant, in which case acute cholecystitis is simulated. This right-sided predilection may reflect variant vascular development, which predisposes to right-sided venous thrombosis.⁷²

CT demonstrates a region of increased attenuation within the greater omentum in the involved segment (Fig. 124-19). This region must be differentiated from an omental primary or secondary malignant neoplasm (e.g., carcinomatosis), omental infection (e.g., tuberculosis), and epiploic appendagitis. The size of the omental abnormality typically is larger in omental infarction and torsion than in epiploic appendagitis.⁷³ See Chapter 62 for a more complete discussion of omental torsion and infarction.

Mesenteric Adenitis

Benign inflammation of the ileocolic lymph nodes can cause mesenteric adenitis, which often simulates appendicitis clinically. *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, and *Helicobacter jejuni* are the most commonly implicated organisms. The appendix is normal, and there may be thickening of the adjacent ileum and cecum. On MDCT, the mesenteric lymph nodes are enlarged (>5 mm), and there may be inflammatory change in the surrounding mesentery (Fig. 124-20).⁷⁴

Infectious Enterocolitides

Gastroenteritis and the infectious enterocolitides are responsible for almost 70% of emergency department visits prompted by abdominal pain. Most cases are self-limited and do not require imaging. In atypical cases, colicky abdominal pain rather than diarrhea may be the predominant symptom. MDCT scans may show normal findings or may show nonspecific mural thickening in more severe cases of infection with invasive *Escherichia coli*, *Shigella*, *Salmonella*, *Yersinia*, and *Entamoeba* organisms.⁷⁵

In pseudomembranous colitis, potent antibiotics disrupt the normal bacterial flora of the colon, resulting in the overgrowth of *Clostridium difficile*. The release of its enterotoxins causes mucosal inflammation and the development of pseudomembranes, consisting of mucus and inflammatory debris. On MDCT, mural thickening averages 15 to 20 mm, with a target or halo pattern caused by submucosal edema.⁷⁵ Contrast material caught between thick haustra may simulate deep ulceration and produce an accordion-like appearance (Fig. 124-21). The lumen may be completely effaced. Ascites and pericolic inflammatory changes accompany these features.⁷⁵ MDCT is most useful in differentiating the panoply of inflammatory, infectious, and neoplastic disorders that can cause acute abdomen in AIDS patients. Infections such as cryptosporidiosis and cytomegalovirus infection produce thickening of the gut wall, edema of the submucosa, and increased enhancement of the mucosa.⁷⁵

Figure 124-21 Pseudomembranous colitis: CT findings. Coronal reformatted CT image shows marked mural thickening with submucosal edema (arrows) of a redundant sigmoid colon. Note the ascites and inflammatory change in the adjacent sigmoid mesocolon.

Neutropenic enterocolitis (i.e., typhlitis) is an acute inflammatory and necrotizing process that affects the cecum or terminal ileum and appendix of immunocompromised patients with profound neutropenia. In this disorder, ulceration of the mucosa is followed by bacterial and fungal invasion. CT features are nonspecific and include segmental mural thickening of the cecum, intramural regions of edema or necrosis, pericolic fluid, and perienteric stranding (Fig. 124-22). In advanced cases, pneumatosis intestinalis and frank perforation may develop.⁷⁵ See Chapter 58 for a discussion of the infectious enterocolitides.

Inflammatory Bowel Disease

Most patients with inflammatory bowel disease experience chronic symptoms punctuated by periodic exacerbations. Fortunately, true emergencies are uncommon, but emergencies are associated with high rates of morbidity and mortality. Bowel obstruction and abscess formation are the most common emergencies for patients with Crohn's disease, whereas fulminant colitis, toxic megacolon, and perforation develop in patients with ulcerative colitis.⁷⁵⁻⁷⁸

Abscesses develop in almost 25% of patients with Crohn's disease, and MDCT is the preferred means of establishing a diagnosis and guiding percutaneous drainage. In patients with obstruction, the status of the diseased bowel, as depicted on MDCT, can significantly influence treatment of the patient. MDCT scans that reveal mural stratification (i.e., the ability to visualize distinct mucosal, submucosal, and muscularis propria layers) indicate the presence of submucosal edema. This edema may improve with steroids, biologic agents, and other immunosuppressive therapy. The reduced edema can lead to widening of the lumen caliber, with subsequent amelioration of the obstruction. If mural stratification is lost, transmural fibrosis is probably present, and the obstruction may require surgery or strictureplasty. MDCT may also reveal other, nonemergent complications of Crohn's disease, including fibrofatty proliferation of the mesentery, fistulas, and reactive adenopathy. In patients with fulminant ulcerative colitis, MDCT is the preferred noninvasive means of assessing the status of the bowel wall and detecting early perforation in toxic megacolon.⁷⁵⁻⁷⁸ See

Figure 124-22 Typhlitis: CT features. Axial scan shows marked mural thickening of the cecum (arrows) in this patient with acute lymphocytic leukemia.

Figure 124-23 Meckel's diverticulitis: CT features. Axial CT image shows a gas-containing abscess (arrow) and inflammatory change in the ileocolic mesentery.

Chapters 41 and 57 for a more complete discussion of inflammatory bowel disease.

Small Bowel Diverticulitis

Small bowel diverticulitis is an unusual condition caused by the inflammation of a jejunal or ileal pseudodiverticulum or Meckel's diverticulum. CT findings are nonspecific and include perienteric inflammation (Fig. 124-23). On occasion, an air-filled or enterolith-filled diverticulum can be identified in the inflammatory process.⁷⁹

Abdominal Aortic Disease

MDCT is superb in depicting thoracoabdominal aortic dissections. Multiplanar reconstructions performed in the sagittal (Fig. 124-24) and coronal planes often help establish the diagnosis.⁸⁰

The clinical triad of symptoms of a ruptured aortic aneurysm includes abdominal pain, a pulsatile mass, and hypotension. Almost one third of patients do not have this classic presentation and are misdiagnosed as having renal colic and diverticulitis. The diagnosis of ruptured aneurysm should be considered for elderly men who are smokers because they run a higher risk of rupture. MDCT is the imaging procedure of choice for patients with suspected aneurysm dissection and rupture. Positive contrast agents should not be administered. Unenhanced images are initially obtained to search for hyperdense blood associated with one of the following signs of impending rupture: the draped aorta sign, in which the posterior wall of the aorta cannot be identified and is closely applied to the spine; the high-attenuation crescent sign (Fig. 124-25), attributed to hemorrhage in mural thrombus or in the wall of the aneurysm, which may be the first sign of aneurysm rupture; and focal discontinuity of intimal calcification.^{81,82}

Rapid infusion of contrast material (>3 mL/s) and thin collimation are required for optimal vascular resolution, depiction

Figure 124-24 Dissection of the infrarenal abdominal aorta. The sagittal reformatted image shows the intimal flap (arrows) in this normal-caliber aorta.

of intimal flaps, and multiplanar, three-dimensional vascular image creation. Although the atherosclerotic walls of aneurysms enhance and are perfused by the vasa vasorum, necrotic areas of the aortic wall reveal nonenhancing focal areas of low density. On MDCT, direct signs of rupture include a retroperitoneal hematoma and frank extravasation of intravenous contrast material (Fig. 124-26).^{81,82}

Hemorrhage

Acute hemorrhage in the gut, mesenteries, omenta, retroperitoneum, or abdominal musculature can cause acute abdomen. Patients with significant bleeding have a declining hematocrit and hypotension. Unenhanced scans should be obtained to detect a hyperdense hematoma. Intravenous contrast material delivered at a high rate (4-5 mL/s) may identify an active site of hemorrhage and provide a useful guide for subsequent angiographic embolization. Bleeding may occur into the rectus sheath or the psoas muscle. Most spontaneous hemorrhages are caused by anticoagulation (Fig. 124-27); however, they may result from tumor hemorrhage, most commonly in cases of renal cell carcinoma and hepatocellular carcinoma.⁸³

Hepatosplenic Vascular Disease

Acute right-sided heart decompensation can lead to dilation of the inferior vena cava and hepatic veins. This can cause hepatic engorgement and distention of Glisson's capsule, an underappreciated cause of right upper quadrant pain. MDCT findings

Figure 124-25 The crescent sign of impending aortic rupture. An aneurysmal infrarenal aorta, photographed at narrow window width, shows a hyperdense thrombus (arrows), which is associated with an increased incidence of rupture.

Figure 124-26 Active rupture of an abdominal aortic aneurysm: CT findings. Contrast material (arrow) is actively extravasating from the left lateral aspect of the aorta. Notice the hemorrhage into the surrounding intraperitoneal, retroperitoneal, subperitoneal, and extraperitoneal spaces.

show the venous dilation and reflux of contrast material into the dilated inferior vena cava and hepatic veins.⁸⁴

Patients with hepatic venous (i.e., Budd-Chiari syndrome), portal venous, and hepatic arterial thrombosis can present with acute right upper quadrant pain. The severity of symptoms depends on the extent and speed of onset of the occlusion.⁸⁵

Budd-Chiari syndrome has many causes, including coagulopathy, polycythemia vera, myeloproliferative disorders, and neoplasms. Thrombus may occur in the hepatic veins and the inferior vena cava. On early scans, the liver shows patchy enhancement, with the central portions having increased enhancement and the periphery having decreased enhancement. Delayed images show a reversal of this pattern.⁸⁵

Figure 124-27 Spontaneous retroperitoneal bleed: CT features. Active extravasation of contrast material (arrow) is identified in the left flank of this patient who was overly anticoagulated. Blood is identified in multiple spaces: retroperitoneal, extraperitoneal, and interfascial.

Figure 124-28 Splenic infarcts: CT findings. Coronal reformatted CT image shows two low-density regions (arrows) within the superior aspect of the spleen in this patient with atrial fibrillation.

Portal vein thrombosis develops in patients with cirrhosis, hepatic neoplasms, pancreatitis, and mesenteric pyelphlebitis. Portal vein thrombosis appears as a low-density central zone surrounded by an enhanced periphery on contrast-enhanced scans. Transient inhomogeneous enhancement of the affected liver segment also occurs. Tumor thrombus may dilate the vein and produce arterial phase enhancement.⁸⁵

Hepatic infarction is rare because the liver has a dual blood supply. Hepatic infarction usually results from thrombosis of the hepatic artery, which can be seen in patients with sepsis, shock, oral contraceptive use, transplanted liver, sickle cell disease, eclampsia, bacterial endocarditis, trauma, and polyarteritis nodosa. MDCT reveals wedge-shaped peripheral areas of low attenuation without contrast enhancement. Splenic and renal infarcts may also be present.⁸⁴

Splenic infarction is manifested as acute left upper quadrant pain but may be clinically silent. Bacterial endocarditis, pancreatitis, portal hypertension, sickle cell disease, and splenomegaly are responsible for most infarcts. On MDCT, focal infarcts are manifested as wedge-shaped zones of decreased attenuation that extend to the splenic capsule (Fig. 124-28). Although some

Figure 124-29 Ureterolithiasis: CT features. A 2-mm stone (arrow) is lodged at the left ureteropelvic junction.

peripheral enhancement may be caused by perfusion of capsular vessels, global infarction can cause diffuse splenic hypodensity.⁸⁶ See Chapter 90 for a more complete discussion of hepatosplenic vascular disorders.

Renal Colic

MDCT has transformed the evaluation of patients with acute flank pain suspected of having acute ureteral obstruction from an impacted stone. MDCT has positive and negative predictive values of more than 95% for the diagnosis of obstructing urinary calculi. MDCT can accurately determine the site and size of ureteral calculi and reveal the cause of flank pain in the 25% of patients without ureterolithiasis (e.g., appendicitis, diverticulitis, pancreatitis, cholecystitis, bowel obstruction, abdominal aortic aneurysms, ovarian disease).⁸⁷⁻⁹⁰

Most calculi are visible on MDCT. They appear as calcifications within the expected course of the ureter (Fig. 124-29). There is typically a thin rim of surrounding soft tissue that represents the edema within the ureteral wall, which strongly favors calcification as a calculus rather than a phlebolith. Secondary signs include hydronephrosis, hydroureter, perinephric stranding, and periureteric stranding. The affected kidney may have an attenuation value lower than that of the unobstructed kidney. A density difference of more than 5 HU is considered significant. Many of these patients are dehydrated, leading to minimal increased medullary attenuation on the normal side and lower attenuation on the obstructed side.⁸⁷⁻⁹⁰

Diagnostic pitfalls include misdiagnosing phleboliths as stones; attributing ureteral dilation to stones when it results from urinary tract infection or inflammation, reflux, or other benign and malignant causes of obstruction; and not detecting calculi that form in patients with human immunodeficiency virus infection undergoing indinavir therapy. The lack of intravenous contrast limits the ability of MDCT to diagnose other acute renal disease, such as pyelonephritis, renal vein thrombosis, and renal infarction. If the initial scan result is normal or inconclusive for the detection of obstructing calculi, a

Figure 124-30 Pyelonephritis: CT features. The infected right kidney is enlarged and edematous, and it produces a diminished, striated nephrogram on this coronal reformatted image.

contrast-enhanced scan can be obtained to search for other causes of the patient's pain (Fig. 124-30). A presumptive diagnosis of recent stone passage can be made when hydroureteronephrosis and perinephric and periureteric stranding are present without a calculus in a patient with clinical improvement and the absence of other findings.⁸⁷⁻⁹²

Conclusions

The subjective nature of pain, its complex neuroanatomic pathways, and the fact that a common symptom can arise from a broad spectrum of diseases make the acute abdomen difficult to diagnose. Nevertheless, two important decisions must be made. Does the patient need surgery, and if so, how soon? Immediate surgery is required for patients with massive hemorrhage (e.g., abdominal aortic aneurysm rupture); other conditions (e.g., perforation, intestinal ischemia) require surgical intervention in a few hours because additional delay increases morbidity. A delay of more than 6 hours is detrimental for patients with disorders such as appendicitis, mesenteric venous thrombosis, and strangulated small bowel obstruction.

MDCT has become the most important noninvasive imaging tool for diagnosing acute abdomen and for answering the questions previously posed. MDCT has the potential to positively affect the outcome, length of stay, and overall health care expenditures of patients with an acute abdomen.

Midgut Hemorrhage

Small Bowel Vascular Lesions

Small Bowel Ulcers

Small Bowel Neoplasms

Lower Gastrointestinal Hemorrhage

Diverticular Hemorrhage

Colon Neoplasms

Gastrointestinal hemorrhage is one of the most common and challenging clinical problems encountered by the gastroenterologist. Approximately 400,000 patients with signs and symptoms of gastrointestinal hemorrhage seek medical attention each year in the United States. Fortunately, in the majority of cases, gastrointestinal hemorrhage resolves spontaneously. However, in 25% of patients with recurrent or persistent bleeding, morbidity and mortality are significant.^{1,2} In these patients, rapid and accurate diagnosis and treatment of the bleeding source are necessary to prevent death and to limit morbidity. In many patients, bleeding may be chronic and intermittent, and patients may present with subtle signs of blood loss, such as anemia. Patients with chronic gastrointestinal blood loss have a lower mortality rate compared with patients with acute bleeding, but the toll on quality of life and the cost of care due to repeated hospitalizations and diagnostic procedures are substantial.

The classification of gastrointestinal hemorrhage is based on the severity of bleeding and the site of bleeding within the gastrointestinal tract. Patients experiencing gastrointestinal blood loss who exhibit signs of hemodynamic instability require rapid resuscitation and prompt identification and treatment of the bleeding site in an inpatient setting. On the other hand,

hemodynamically stable patients with signs of chronic blood loss may be managed as outpatients.

On the basis of endoscopic accessibility, gastrointestinal tract bleeding is also classified by the segment of the gastrointestinal tract in which the bleeding occurs. Upper gastrointestinal tract bleeding is defined as bleeding that originates from a lesion proximal to the ligament of Treitz, that is, the segment of bowel routinely accessible by upper endoscopy. Midgut bleeding occurs between the ampulla of Vater and the terminal ileum (accessible by deep endoscopy); and lower gastrointestinal tract bleeding occurs distal to the terminal ileum (accessible by colonoscopy). The approximate frequency of bleeding in each of these segments is 75% to 80%, 5% to 10%, and 20% to 25%, respectively.

The remainder of this chapter discusses an approach to the diagnosis and treatment of patients with gastrointestinal hemorrhage with emphasis on the imaging tools used to detect the nature and location of bleeding and the common methods used in the treatment of gastrointestinal hemorrhage.

Etiology

The list of gastrointestinal bleeding sources is extensive (Table 125-1). Most disorders are more common in specific segments of the gastrointestinal tract, and the more common conditions responsible for bleeding are discussed in the appropriate sections.

Past medical history often provides helpful clues to the source of gastrointestinal bleeding. Up to 60% of patients with a history of upper gastrointestinal hemorrhage bleed from the same lesion.³ Comorbid conditions may also suggest a potential cause of bleeding:

- Liver disease or alcohol abuse: varices
- Renal disease, aortic stenosis, or Osler-Weber-Rendu disease: angiodysplasia
- Abdominal aortic aneurysm or aortic graft: aortoenteric fistula
- *Helicobacter pylori* infection: peptic ulcer disease
- Smoking, alcohol abuse, *H. pylori* infection: malignant disease
- Gastroenteric anastomosis: marginal ulcers
- Chronic diarrhea and abdominal pain: inflammatory bowel disease

Clinical Presentation and Evaluation

Gastrointestinal hemorrhage has five clinical presentations: hematemesis, which is bloody vomitus that may be fresh and bright red or older with a coffee-ground appearance; melena, which is black, shiny, sticky, foul-smelling fecal matter that results from the degradation of blood in the gut; hematochezia, which is the passage of bright red or maroon blood, bloody

TABLE 125-1 Causes of Gastrointestinal Hemorrhage**Upper Tract Hemorrhage**

Duodenal ulcer
 Gastric ulcer
 Gastritis
 Marginal ulcer
 Esophagitis
 Esophageal and gastric varices
 Mallory-Weiss tear
 Barrett's ulcer
 Hematobilia
 Ménétrier's disease
 Hiatal and paraesophageal hernias

Upper and Lower Tract Hemorrhage

Neoplasms
 Carcinoma
 Leiomyosarcoma, leiomyoma
 Hemangioma
 Lymphoma
 Metastases
 Polyps
 Aortoenteric fistulas
 Vascular anomalies
 Osler-Weber-Rendu syndrome
 Blue rubber bleb nevus syndrome
 CRST syndrome (calcinosis cutis, Raynaud's phenomenon, sclerodactyly, and telangiectasia)
 Angiodysplasia
 Arteriovenous malformations
 Amyloidosis
 Elastic tissue disorders
 Pseudoxanthoma elasticum
 Ehlers-Danlos syndrome
 Hematologic disorders and diatheses
 Vasculitides

LOWER TRACT HEMORRHAGE

Hemorrhoids
 Anal fissures
 Diverticulosis of the small bowel and colon
 Ischemic bowel disease
 Inflammatory bowel disease
 Solitary colonic ulcer
 Intussusception

Modified from Rockey DC: Gastrointestinal bleeding. In Feldman M, Friedman LS, Brandt LJ (eds): *Gastrointestinal and Liver Disease*, 8th ed. Philadelphia, Saunders, 2010, pp 247–298.

diarrhea, or blood mixed with formed stool; occult blood, found only by testing of the stool with a chemical reagent; and symptoms of blood loss, such as dyspnea, dizziness, or shock (in massive bleeding) or iron deficiency anemia (in chronic bleeding).⁴⁻⁷

A major goal in the diagnosis of gastrointestinal hemorrhage is differentiation of upper from more distal gastrointestinal tract sources of bleeding. Proximal lesions tend to cause hematemesis or melena, whereas distal lesions more commonly produce hematochezia. Hematochezia stemming from an upper gastrointestinal source usually reflects a massive hemorrhage, which, if it is associated with a bloody nasogastric aspirate, has a mortality of nearly 30%. Hematemesis almost invariably localizes the source of hemorrhage proximal to the ligament of Treitz. However, up to 40% to 50% of patients with upper gastrointestinal bleeding do not experience hematemesis. About 20% of patients with bleeding ulcers present with melena, 30%

with hematemesis, 50% with both, and as many as 5% with hematochezia.⁸⁻¹¹ Melena can result when as little as 50 mL of blood is instilled into the upper gastrointestinal tract; the instillation of 1000 mL or more leads to hematochezia.

Aspiration of gastric contents with a nasogastric tube may reveal blood, which is diagnostic of an upper gastrointestinal bleeding source. The absence of blood, however, does not entirely exclude the possibility of an upper gastrointestinal hemorrhage because the bleeding might have ceased before passage of the tube or might have occurred distal to a competent pyloric sphincter. The presence of bile in the gastric aspirate indicates that the bowel distal to the pylorus has been sampled. Nasogastric lavage may help clear the stomach of blood clots and debris before endoscopy; however, there is little evidence to suggest that lavage helps stop bleeding.

Diagnostic and Therapeutic Procedures

ENDOSCOPY

Upper endoscopy and colonoscopy are the most important tools for evaluation of patients with gastrointestinal bleeding because they permit direct visualization of the bowel lumen and provide a method for rapid diagnosis and treatment of abnormalities within the upper gastrointestinal tract and within the colon and terminal ileum. Endoscopy can determine the cause of bleeding with a 90% to 95% accuracy while affording access for therapeutic procedures and providing valuable prognostic information.¹⁰

Whereas endoscopy remains the cornerstone of diagnosis and therapy for gastrointestinal bleeding originating in the upper gastrointestinal tract and colon, until recently the small bowel has been inaccessible. Recent advances in endoscopic techniques, including capsule endoscopy and deep enteroscopy, have extended the usefulness of endoscopy to the entire gastrointestinal tract, including the small bowel.

CAPSULE ENDOSCOPY

Capsule endoscopy (CE) was introduced in 2000 and enables visualization of the entire gastrointestinal tract, including the small bowel, which until then was virtually inaccessible with conventional endoscopic techniques. This technique involves the oral or endoscopic introduction of a small capsule equipped with a light source, lens, battery, radiofrequency transmitter, and antenna into the stomach or duodenum. The capsule acquires images of the gastrointestinal tract at two frames per second and transmits data to a data recorder worn on the patient's waist. The images are then downloaded and viewed on a computer. CE allows visualization of the entire small bowel in 79% to 90% of patients.¹²

CE does have several disadvantages. Trivial findings are commonly detected and occur in up to 23% of healthy patients undergoing CE.¹³ In addition, because the device is purely diagnostic, additional therapeutic procedures may be indicated if significant abnormalities are found. The most serious disadvantage of CE is capsule retention in patients with a stricture or bowel obstruction, sometimes requiring surgical removal. This is more common in patients with Crohn's disease and small bowel tumors. Patency capsules are useful for minimizing the

risk of retention by selecting those patients who may safely undergo CE.¹⁴

DEEP ENTEROSCOPY

These techniques, used primarily to evaluate the small bowel, include double-balloon enteroscopy (DBE), single-balloon enteroscopy, and spiral enteroscopy. These techniques offer an advantage over CE because they not only permit visualization of the entire small bowel but also allow therapeutic interventions. These advanced techniques require special technical skill and have associated complications, such as bleeding and bowel perforation; therefore, they are usually performed only after a positive finding on CE or other imaging studies suggesting a small bowel abnormality.

Double- and single-balloon enteroscopes consist of an enteroscope and an overtube with an inflatable balloon. Double-balloon enteroscopes also have a balloon attached to the end of the enteroscope. Advancement through the small bowel is achieved by a series of push-pull maneuvers in which the balloon is alternately inflated and deflated as the enteroscope and overtube are advanced as the small bowel is shortened like the bellows of an accordion. These procedures can be performed by an antegrade or retrograde approach. The antegrade approach is selected for suspected lesions in the proximal 75%; the retrograde approach is selected for distal lesions. The choice of approach is based on CE or other imaging findings. The success rate for examination of the entire small bowel ranges from 16% to 86%.¹⁵ The complication rate for diagnostic DBE is 0.8%; for therapeutic procedures, it is 4%.

Spiral enteroscopy is a new technique using a spiral overtube, which has a 21-cm raised helix at the distal end. The overtube is placed over the enteroscope, and the paired device is advanced by rotation in a clockwise fashion until the farthest extent of the small bowel is reached. The enteroscope is then advanced alone, followed by rotation of the spiral overtube. This device permits significantly shorter examination time and has a complication rate similar to that of DBE.

MULTIDETECTOR COMPUTED TOMOGRAPHY

The utility of multidetector computed tomography (MDCT) in the diagnosis of gastrointestinal hemorrhage has become increasingly accepted. In a meta-analysis of 22 studies involving 672 patients with acute episodes of gastrointestinal bleeding, CT angiography achieved a sensitivity of 85% and specificity of 92% in detecting active bleeding.¹⁶ MDCT techniques also appear useful in evaluating the source of bleeding in hemodynamically stable patients. In a prospective study of outpatients with obscure gastrointestinal bleeding, multiphase CT enterography (CTE) identified a bleeding source in 14 of 16 patients.¹⁷

In the majority of reports, the method used for evaluation of gastrointestinal bleeding is a modification of CTE technique¹⁸ (see Chapter 38). The patient drinks a large volume of low-concentration barium solution (e.g., VoLumen) to produce bowel distention. Water can be substituted, but it produces suboptimal bowel distention because of rapid intestinal absorption. Both agents are of neutral density to permit optimal bowel wall visualization. The presence of positive contrast material within the bowel, as is common with most CT scan studies, obscures the bowel wall and may mask subtle vascular lesions and prevent the identification of active bleeding.

A variety of scan techniques for evaluation of gastrointestinal bleeding have been reported. These usually involve two- or three-phase acquisitions (e.g., arterial, portal venous, delayed) after intravenous administration of contrast material, sometimes combined with a preliminary noncontrast scan. Obviously, the greater the number of acquisitions, the higher the patient's radiation dose. However, a greater number of acquisitions may improve detection of a bleeding source. The evolving appearance of active bleeding producing intraluminal accumulation of contrast material is best appreciated over time with multiple scan acquisitions (Fig. 125-1). Also, some lesions have characteristic enhancement patterns that may permit a specific diagnosis and therefore encourage timely management. In addition, vascular lesions may be visible only transiently, and abnormalities may go undetected if the acquisition is too early or too late.¹⁹ The choice of technique depends on the patient's age and clinical history. In our practice, we prefer to use three-phase acquisition for the evaluation of the majority of patients with obscure gastrointestinal bleeding.¹⁷

NUCLEAR SCINTIGRAPHY

Radionuclide imaging in the evaluation of gastrointestinal hemorrhage can be classified into direct and indirect methods. Direct nuclear scintigraphic methods use either technetium Tc 99m sulfur colloid or the preferred ^{99m}Tc-labeled red blood cell (RBC). Indirect evaluation of gastrointestinal blood loss relates to the use of ^{99m}Tc-pertechnetate scintigraphy in suspected Meckel's diverticulum, which is of particular value in younger patients.²⁰

^{99m}Tc-sulfur colloid studies can be useful in demonstrating rapid gastrointestinal blood loss, but with a short intravascular residence time (half-life of 2-3 minutes) and increasing uptake in the bone marrow, liver, and spleen, it has limited usefulness in gastrointestinal blood loss, as active bleeding is almost always intermittent. This allows a limited imaging window of approximately 15 minutes to demonstrate the bleeding site. It is also an "off-label" indication for this radionuclide tracer.

^{99m}Tc-labeled RBC scintigraphy is considered a sensitive noninvasive method for detection of gastrointestinal blood loss, with sensitivity ranging from 40% to 90%. In the animal model, it can detect blood loss rates on the order of 0.1 mL/min compared with 0.5 to 1.0 mL/min with contrast angiography.²¹⁻²⁶

The examination requires little preparation of the patient, has relatively low radiation exposure (0.3 rad/20 mCi), and can usually cover more than 12 hours of intermittent imaging. Sensitive imaging is predicated on high and durable RBC labeling efficiency, on the order of 95% by postlabeling quality control. The highest labeling efficiency is by the *in vitro* labeling methodology with use of a commercial kit such as UltraTag (Mallinckrodt, St. Louis, MO). The labeling procedure takes 20 to 30 minutes, and the labeled RBCs are reinjected, acquiring anterior abdominal dynamic images under a large field of view gamma camera. Typically, 60 to 90 minutes of initial imaging is standard, with subsequent delayed images if initial images are normal, as dictated by the patient's clinical status.²⁷

Image interpretation relies on viewing extravasation of the tracer into the bowel with subsequent peristaltic movement through the bowel (Fig. 125-2). The configuration, location, and movement of the tracer over time determine whether the gastrointestinal bleeding site is from the small or large bowel,

Figure 125-1 Active colonic bleeding. Sequential 5-minute dynamic composite anterior ^{99m}Tc -labeled RBC images in a patient with active gastrointestinal blood loss. Note the prompt appearance of abnormal tracer uptake in the right lower quadrant (arrow) with subsequent antegrade movement of tracer from the cecal region through the right colon to the transverse colon (arrowheads).

Figure 125-2 Active small bowel bleeding. An 82-year-old woman taking warfarin for aortic valve replacement experienced melena and anemia; findings on capsule endoscopy were normal. Axial arterial (A), enteric (B), and delayed (C) phase images from multiphase CTE demonstrate progressive accumulation of contrast material in the dependent portion of the bowel (arrow and arrowheads) due to active bleeding from an ileal ulcer. (From Huprich J, Fletcher J, Fidler J, et al: Prospective blinded comparison of wireless capsule endoscopy and multiphase CT enterography in obscure gastrointestinal bleeding. *Radiology* 260:744–751, 2011.)

noting that both antegrade and less commonly retrograde tracer movement can occur.

Imaging pitfalls can be due to free technetium within the stomach and renal system. This may be seen with a poor ^{99m}Tc -RBC label, unusual or prominent blood pool foci (such as abdominal aortic aneurysm), esophageal varices, penile activity, and vascular grafts as well as with miscellaneous items such as accessory splenic tissue and hemangiomas.

ANGIOGRAPHY

Persistent or recurrent bleeding occurs in 7% to 16% of patients with upper gastrointestinal bleeding²⁸ and in up to 25% of patients with lower gastrointestinal bleeding.²⁹ Such patients may require angiographic intervention to locate or to treat the source of bleeding.

In most cases, angiographic control of gastrointestinal bleeding requires that the site of bleeding first be identified. Angiographic detection of active bleeding requires a minimum bleeding rate of 0.5 mL/min. Because isotope-labeled RBC scans can detect lower bleeding rates (0.1 mm/min), a positive nuclear study may predict a positive angiographic examination.

Therapeutic angiographic intervention has a wide spectrum of applications, from embolization of arterial lesions, to direct infusion of vasopressin, to performing a transjugular intrahepatic portal systemic shunt (TIPS). Intra-arterial vasopressin causes generalized vasoconstriction by a direct action on vessel walls, thereby decreasing perfusion pressure to all stable clot formation. Unfortunately, rebleeding is common after cessation of the infusion. As a potent peripheral vasoconstrictor, vasopressin must be used with caution in patients with coronary artery disease, congestive cardiomyopathy, severe hypertension, and peripheral vascular disease.

Therapeutic embolization causes mechanical occlusion of the blood supply to the bleeding site. The embolic agents used can produce temporary (0-21 days) or permanent vessel occlusion. The embolic agent is delivered through an end-hole catheter into the target vessel. Complications occur in 5% to 9%, with ischemia and infarction being the most common. The use of superselective catheters has decreased complications related to ischemia. The use of angiography in specific cases of gastrointestinal bleeding is discussed in the following sections.

BARIUM STUDIES

Barium studies have no significant role to play in assessing the patient with massive gastrointestinal hemorrhage. Barium in the bowel lumen interferes with endoscopic studies, diagnostic MDCT, and diagnostic and therapeutic angiography.³⁰⁻³² In patients with anemia and occult gastrointestinal bleeding, barium studies have been replaced by upper gastrointestinal endoscopy, colonoscopy, CE, and MDCT.

Upper Gastrointestinal Hemorrhage

Upper gastrointestinal tract bleeding constitutes 75% to 80% of all cases of acute gastrointestinal tract bleeding. The incidence has decreased significantly in recent times; however, the mortality rate from acute nonvariceal upper gastrointestinal tract bleeding has decreased only minimally in the past 50 years, ranging from 2.5% to 10%.^{33,34} This lack of change in mortality rate likely is related to the increasing age of patients

who present with upper gastrointestinal bleeding and an increase in associated comorbid conditions.

Peptic ulcers are the most common source of upper gastrointestinal bleeding, accounting for 20% to 40% of cases. Other major causes are gastric erosions (15%-25% of cases), bleeding varices (5%-30%), and Mallory-Weiss tears (5%-15%). The use of aspirin or nonsteroidal anti-inflammatory drugs is prevalent in 45% to 60% of all cases of acute upper gastrointestinal bleeding. Moreover, the risk of upper gastrointestinal bleeding is increased in patients who take as few as one "baby aspirin" (81 mg) per day.

The initial evaluation of a patient with upper gastrointestinal bleeding should focus on assessment of hemodynamic status and comorbid conditions. Factors associated with severe upper gastrointestinal bleeding include red blood from nasogastric lavage, tachycardia, and hemoglobin level below 8 g/dL.

As in all cases of gastrointestinal bleeding, consideration must be given to comorbid illnesses that predispose patients to hypoxia (coronary artery disease, chronic obstructive pulmonary disease), volume overload (congestive heart failure, renal failure), bleeding (coagulopathies, thrombocytopenia, liver disease), and aspiration (dementia, hepatic encephalopathy) in choosing diagnostic and therapeutic procedures.

Expedited use of upper endoscopy is the diagnostic procedure of choice for acute upper gastrointestinal bleeding. Its reported sensitivity and specificity for the diagnosis of upper gastrointestinal bleeding are 92% to 98% and 30% to 100%, respectively.² In addition, once bleeding is identified, endoscopic treatment can achieve hemostasis and prevent recurrent bleeding in most patients.

Urgent endoscopy, however, cannot be advocated for all patients with acute upper gastrointestinal hemorrhage. Several prospective, randomized studies published in the early 1980s failed to demonstrate a decrease in morbidity or mortality rates associated with endoscopy in diagnosis of upper gastrointestinal hemorrhage.³⁵

Upper gastrointestinal endoscopy, however, should be performed as soon as possible in high-risk individuals: alcoholic patients who may be bleeding from a variety of sources; patients with suspected aortoenteric fistula; those with a quantitatively large volume of blood loss; those with suspected active hemorrhage; and those experiencing or unlikely to tolerate a recurrent hemorrhagic episode, including those who object to blood transfusions on religious grounds.³⁶ Patients with minor bleeding (i.e., without tachycardia, hypotension, or decreased hematocrit) can wait until the next day for elective endoscopy. Younger, otherwise healthy patients with trivial bleeding can be discharged without diagnostic testing with outpatient follow-up evaluation.³⁷

PEPTIC ULCERS

Bleeding from gastric or duodenal ulcers remains the most common cause of upper gastrointestinal tract hemorrhage. The most common risk factors for peptic ulcer disease are *Helicobacter pylori* infection, nonsteroidal anti-inflammatory drugs, physiologic stress, and excess gastric acid (e.g., Zollinger-Ellison syndrome).

The approach to a patient who has bled from peptic ulcer disease is determined at the time of endoscopy. There are many options for endoscopic therapy. Thermal-coaptive coagulation (an endoscopic technique used to ablate bleeding ulcers in

which two vessel walls are compressed and “fried”) involves the placement of the coagulating probe directly on the bleeding vessel. This is uniformly effective for vessels up to 2 mm in diameter with the heater probe. Injection therapy results in short-term tamponade and vasospasm and can be induced with the liberal use of epinephrine (1:10,000). Vasodestruction is long term and can be induced by sclerosants or alcohol (total injection volume not to exceed 2 mL). Endoscopic clipping has not been shown to be any more effective than thermal therapy³⁸; however, it may have appeal for use in patients with coagulation disorders or in cases in which further coaptive coagulation may not be desirable.

Endoscopic therapy is indicated for patients with active arterial bleeding and those with a nonbleeding visible vessel (pigmented protuberance). An adherent clot is a predictor of rebleeding and can be managed with endoscopic therapy or high-dose proton pump inhibitor therapy (or both).³⁹⁻⁴¹ All three endoscopic treatment options have been shown to have a relatively similar efficacy. However, epinephrine injection, followed by a more permanent form of treatment (coagulation, vasodestruction, or clipping), has been shown to be more effective than epinephrine therapy alone.⁴² Patients with a clean ulcer base (rebleeding rates, <5%) and a flat pigmented spot (rebleeding rates, 5%-10%) do not require endoscopic therapy and probably could be discharged soon after endoscopy. Deep ulcers may tend to expose larger vessels that may not be amenable to endoscopic coagulation. Deep ulcers in the stomach, particularly those in the upper body on the lesser curvature (left gastric artery), or posterior duodenal bulb (gastroduodenal artery) with nonbleeding visible vessels more than 2 to 3 mm in diameter should not be treated endoscopically. These patients may benefit from therapeutic embolization.

Rebleeding after endoscopic therapy occurs 20% to 30% of the time. Re-treatment for recurrent bleeding achieves long-term hemostasis in more than 70% of cases.⁴³ The endoscopic appearance of the ulcer may predict its likelihood of rebleeding. An endoscopically visualized, actively bleeding ulcer carries an 80% chance of persistent or recurrent bleeding.¹¹ A nonbleeding visible vessel is associated with a 50% chance of rebleeding.^{11,13}

If endoscopic therapy fails, angiographic embolization of the bleeding vessel is a preferable option to surgical intervention.³⁸ Vasopressin is effective at controlling gastric bleeding (70%). Bleeding duodenal ulcers are relatively unresponsive to vasopressin infusion because of the dual blood supply to the duodenum; the inflammatory reaction produced by the penetrating ulcer; and the large size of the vessels involved, which do not constrict in response to the vasopressin. However, rebleeding is common. Initial control of upper gastrointestinal bleeding with embolization can be achieved in 84%; however, rebleeding occurs in 27%.⁴⁴

ESOPHAGEAL VARICES

Portal hypertension develops from an increase in resistance to portal venous outflow from both mechanical and vascular factors and is maintained by a systemic hyperdynamic circulation and peripheral vasodilation. A hepatic venous pressure gradient of at least 10 mm Hg is required for the development of esophageal varices, and a gradient of at least 12 mm Hg is generally required for the development of variceal bleeding. Gastroesophageal varices are present in approximately half of

cirrhotic patients, and variceal hemorrhage occurs at a rate of 5% to 15% per year. Although survival has improved in recent years, variceal bleeding is associated with a mortality of at least 20% at 6 weeks.⁴⁵ Variceal size, endoscopic stigmata, and advanced liver disease are predictors of variceal bleeding.

Prophylactic treatment of patients with varices without bleeding is recommended with nonselective β -adrenergic blockers, which decreases portal venous pressure. These agents should be used in patients with small varices with a higher risk of bleeding, specifically those with red wale signs or those with advanced liver disease. Bleeding prophylaxis is similarly recommended for patients with large varices with either β blockade or variceal band ligation.

Therapy for acute esophageal variceal bleeding includes vasoactive drug treatment (octreotide in the United States) for 2 to 5 days, endoscopic variceal band ligation, and prophylactic antibiotics. A percutaneously placed TIPS is used for the 10% to 20% of patients who fail to respond to the standard therapy. In those with advanced liver disease, TIPS may potentially have a survival advantage over standard therapy.⁴⁵ Endoscopic variceal band ligation with or without β blockade is used for the prevention of rebleeding. Acute gastric variceal bleeding should be managed with pharmacologic therapy and antibiotics as well. Gastroesophageal and fundic varices can undergo banding acutely. Isolated gastric varices can be treated in the face of active bleeding with cyanoacrylate glue (not currently available in the United States). TIPS is used to prevent rebleeding from gastric varices. There are concerns with TIPS regarding shunt clotting, worsening hepatic encephalopathy, and deterioration of liver function.

GASTRITIS

Gastric mucosal bleeding attributable to stress, alcohol abuse, and use of nonsteroidal anti-inflammatory agents accounts for almost 30% of major gastrointestinal hemorrhage. The superficial erosions result from the breakdown of the mucosal barrier, allowing back diffusion of acid into the submucosa. Most patients with diffuse gastritis stop bleeding spontaneously. If they do not, transcatheter therapy should be attempted because surgery has a high mortality rate (21%) in this setting.⁴⁶

Diffuse hyperemia of the mucosa is seen angiographically in patients with hemorrhagic gastritis. If no extravasation of contrast medium is seen, intra-arterial injection of vasopressin should be performed. Embolization should be used in patients with active extravasation. These techniques are successful in approximately 80% of patients.

MALLORY-WEISS TEAR

Mallory Weiss syndrome is characterized by longitudinal mucosal lacerations in the distal esophagus and proximal stomach. Patients usually have a history of recent retching or vomiting and present with excruciating epigastric and left-sided chest pain radiating to the back. This condition accounts for approximately 5% of upper gastrointestinal tract bleeding. Diagnosis is made endoscopically.

Forty percent to 70% of patients with Mallory-Weiss syndrome require blood transfusion; however, 75% to 80% of patients are successfully treated with bed rest, sedation, and vigorous fluid and blood replacement.⁴⁷ Endoscopic treatment, with the injection of epinephrine or ethanol followed by thermal

coagulation, is successful in the majority of cases that fail conservative treatment. In rare cases in which endoscopy fails to staunch the hemorrhage, diagnostic and therapeutic angiography is indicated. After the bleeding vessel (usually a branch of the left gastric artery) is identified, a nonpermanent embolic agent such as Gelfoam pledgets should be used because this disorder is self-limited. Because the blood supply to the esophagus is complex, intra-arterial injection of vasopressin usually is not successful.

Midgut Hemorrhage

In approximately 5% of patients presenting with gastrointestinal bleeding, no bleeding source is identified at upper endoscopy and colonoscopy. This condition is defined by the American Gastroenterological Association as obscure gastrointestinal bleeding.⁴⁸ Repeated endoscopy may reveal a bleeding source missed at initial endoscopy in 15%, usually located in the upper gastrointestinal tract. Of the remaining patients, 75% will have a small bowel source for blood loss. Angiectasias (also called angiodysplasia) are the most common cause of bleeding in patients older than 65 years (54%), followed by small intestinal ulcers (13%) and tumors (12%). In patients younger than 41 to 64 years of age, angiectasias (35%) and small bowel tumors (31%) are most common. Before the age of 40 years, Crohn's disease is the most common cause of small bowel bleeding (34%), followed by small bowel tumors (23%) and nonspecific enteritis (11%).⁴⁹

In the majority of patients with a small bowel bleeding source, blood loss is slow and chronic. They may present with iron deficiency anemia with or without melena or hematochezia. In these patients, wireless CE is the preferred initial diagnostic procedure. The yield of CE in obscure gastrointestinal bleeding is up to 90% if it is performed within 1 to 2 weeks of the bleeding episode and drops to 60% to 70% if it is performed more than 2 weeks after the bleeding event.^{50,51} In patients with normal examination findings, repeated CE has been recommended and may reveal significant abnormalities in 55%.⁵²

Overall, CE outperforms CT enteroclysis in evaluation of patients with obscure gastrointestinal bleeding presenting with iron deficiency anemia, with sensitivities of 78% and 22%, respectively.⁵³ A pooled analysis of 24 CE trials reported an overall yield of 87% in obscure gastrointestinal bleeding.⁵⁴ Multiphase CTE may have a complementary role to CE in evaluating patients with suspected small bowel bleeding because of its ability to detect submucosal masses that may go undetected by CE. CE may fail to detect significant small bowel masses, particularly as some small bowel tumors, such as carcinoids and gastrointestinal stromal tumor, may not have a mucosal component.⁵⁵⁻⁵⁷ A total of 19 false-negative CE examinations were described in three reports, and 18 of 19 (95%) missed lesions were masses. Ross and coworkers⁵⁸ reported false-negative CE findings in 10 of 15 patients (67%) with small bowel tumors. In a retrospective study of 17 patients with small bowel tumors who underwent both CTE and CE, sensitivities were 94% and 35%, respectively.⁵⁹ In another prospective study comparing multiphase CTE with CE in obscure gastrointestinal bleeding, CTE detected 9 of 9 small bowel tumors compared with 3 of 9 for CE.¹⁷ Therefore, patients with normal findings on CE should be considered for multiphase CTE to exclude disease missed by CE, especially neoplasms.

Patients with signs of mild blood loss, such as iron deficiency anemia, in which a neoplasm has been excluded, may be considered for medical therapy. In patients in whom a small bowel neoplasm cannot be excluded or in whom bleeding is significant, requiring ongoing transfusions, additional more invasive procedures are warranted.

Deep enteroscopy can be performed by DBE, single-balloon enteroscopy, or spiral enteroscopy. The choice depends on the available expertise. DBE is the most widely used, and therefore most reports in the literature are based on this technique. The diagnostic yield of DBE in patients with obscure gastrointestinal bleeding ranges from 60% to 80%.

Angiography is used primarily to confirm the presence of a small bowel vascular lesion, especially arterial lesions. If such a lesion is detected on the angiogram in the clinical setting of acute gastrointestinal hemorrhage and no other lesion is found, catheter embolization is indicated even if acute hemorrhage is not detected at that time. However, if the lesion cannot be safely embolized, a microcatheter can be secured and the patient taken to surgery for methylene blue injection at the time of operative exposure to identify the short segment of bowel to be resected.⁶⁰

Intraoperative enteroscopy can be used in cases of failed enteroscopy. It allows the highest success rate in evaluating the entire small bowel. Rebleeding after therapeutic surgical intervention is low compared with deep enteroscopy. However, surgery is associated with higher morbidity than other therapies are.

SMALL BOWEL VASCULAR LESIONS

Vascular lesions of the small bowel include angiectasias, arterial lesions (arteriovenous malformations and Dieulafoy lesions), and venous lesions (venous angiomas and small bowel varices). Endoscopy and CTE appear to be complementary in detection of these lesions.¹⁹

Angiectasias are the most common vascular lesion associated with obscure gastrointestinal bleeding. Angiectasias can occur anywhere in the gastrointestinal tract. Much of what we know about angiectasias (also known as angiodysplasias) is based on findings at colonoscopy,⁶¹ although there is no evidence to suggest that small bowel angiectasias differ in any significant way from colonic lesions. Angiectasias consist of thin tortuous veins that lack an internal elastic layer. Peak incidence of these lesions is in the seventh and eighth decades of life. Reports indicate that angiectasias are multiple in 40% to 75% of patients with gastrointestinal bleeding. In addition, angiectasias are seen at colonoscopy in 2.6% to 6.2% of patients having the procedure performed for a variety of indications.⁶¹ Angiectasias appear as tiny focal areas of enhancement within the bowel wall (Fig. 125-3). On endoscopic examination, angiectasias consist of punctate or patchy areas of erythema, 2 to 10 mm in size. Angiectasias are treated endoscopically with ablation therapy. Unfortunately, recurrent bleeding is common.

Arterial lesions include arteriovenous malformations and fistulas and Dieulafoy lesions and are much less common than angiectasias. Dieulafoy lesions are most common in the stomach but can be seen throughout the gastrointestinal tract. They are a rare cause of obscure gastrointestinal bleeding. These lesions may be congenital and consist of a submucosally located artery with overlying ulceration. They are estimated to occur in 3.5% of patients with obscure gastrointestinal bleeding.⁶²

Figure 125-3 Angioectasia. A 65-year-old woman with multiple episodes of melena. Arterial (A), enteric (B), and delayed (C) phase axial images from a multiphase CTE study demonstrate a focal, less than 5 mm nodular area of enhancement in the distal jejunum (arrows), undetectable on the arterial phase and brightest on the enteric phase. Angioectasia was subsequently ablated during balloon-assisted endoscopy. (From Huprich J, Barlow J, Hansel S, et al: Multiphase CT enterography of small bowel vascular lesions. *AJR* 201:65–72, 2013.)

Figure 125-4 Dieulafoy lesion. A 58-year-old man with hematochezia. Arterial (A), enteric (B), and delayed (C) phase axial images from a multiphase CTE study demonstrate a small nodular area of enhancement in the distal jejunum visible only on the arterial phase (large arrow). Adjacent linear collection of contrast material (small arrow) may represent active bleeding. (From Huprich J, Barlow J, Hansel S, et al: Multiphase CT enterography of small bowel vascular lesions. *AJR* 201:65–72, 2013.)

Arterial lesions have characteristic findings on multiphase CTE, enhancing brightly on arterial phase images and fading or disappearing on subsequent phases (Fig. 125-4). Therefore, arterial lesions may go undetected if arterial phase images are omitted. Arteriovenous malformations and fistulas may be accompanied by an early draining vein, which distinguishes them from Dieulafoy lesions. Because arterial lesions are exposed to high arterial pressure, there is a significant potential for life-threatening bleeding. Treatment consists of endoscopic laser or mechanical ablation, embolization, or surgical resection.

Venous lesions consist of small bowel varices and venous angiomas. Small bowel varices form within adhesions in the setting of mesenteric venous hypertension because of either mesenteric venous obstruction or portal hypertension. Adhesions between adjacent bowel loops or between the bowel and peritoneum provide a pathway for the varices to form. Small

bowel varices should be suspected in patients who have had prior abdominal surgery and have evidence of mesenteric venous hypertension.⁶³ Venous angiomas are rare lesions of the small bowel that may occur in isolation or may be associated with Klippel-Trénaunay or blue rubber bleb nevus syndrome. The lesions are classified pathologically as hamartomas and consist of large blood-filled sinuses lined by endothelial cells. Venous lesions are usually treated by surgical resection.

SMALL BOWEL ULCERS

Ulcerations of the small bowel are a common cause of bleeding. Whereas there are many causes, nonsteroidal anti-inflammatory drugs are probably the most common cause of small bowel ulceration. Patients may present with small bowel obstruction due to associated strictures. Diagnosis of small bowel ulcerations is made by endoscopy. Radiology does not

play a significant role in diagnosis or management of ulcers. Enteroclysis techniques may be helpful in detecting those with associated strictures. Segmental resection of the affected small bowel may be necessary to avoid stricturing.

SMALL BOWEL NEOPLASMS

Small bowel neoplasms are the second most common lesions associated with obscure gastrointestinal bleeding. Most small bowel neoplasms are potentially malignant; therefore, their detection is important not only to treat the bleeding but also to minimize morbidity and mortality due to disease progression. Small bowel tumors are discussed elsewhere in the text.

Lower Gastrointestinal Hemorrhage

Lower gastrointestinal bleeding represents approximately 25% of all gastrointestinal bleeding and is associated with a significantly lower mortality (4%) compared with upper gastrointestinal bleeding. Bleeding will stop spontaneously in 80% to 85% of patients with lower gastrointestinal bleeding.⁶⁴ Compared with upper gastrointestinal bleeding, patients with lower gastrointestinal bleeding are older, which is probably explained by the increasing prevalence of colonic diverticulosis and angiodysplasia with age.

The majority of patients with hematochezia have a lower gastrointestinal bleeding source. As stated before, patients with hematochezia will usually undergo nasogastric lavage to exclude massive upper gastrointestinal bleeding. Blood originating from the left colon is usually bright red, whereas bleeding from the right colon is dark or maroon-colored owing to the more prolonged transit. However, rapid transit from massive right-sided bleeding may be bright red, and bleeding from the cecum can rarely appear as melena. Bacterial metabolism needs sufficient time for melena to be generated from fresh blood. If blood is limited to the toilet paper or surface of formed stool, a perianal source is likely. Tenesmus suggests a rectal origin (e.g., proctitis).

In a review of several large series, the most common causes of hematochezia were diverticulosis (42%), ischemic colitis (18%), anorectal disorders (hemorrhoids, fissure, rectal ulcers; 16%), neoplasms (11%), and angiodysplasias (3%).⁶⁵

After initial resuscitation and exclusion of an upper gastrointestinal bleeding source, colonoscopy is the procedure of choice for evaluation of hematochezia. A definite or potential bleeding source is seen at colonoscopy in 45% to 90% of patients with lower gastrointestinal bleeding.⁶⁵ The benefit of performing urgent colonoscopy is unclear. Some clinicians perform colonoscopy on an unprepared bowel; however, studies of colonoscopy for lower gastrointestinal bleeding without bowel cleansing report lower success rates. Most centers perform colonoscopy after adequate bowel preparation has been given. In patients in whom colonoscopy is incomplete or unsuccessful who continue to bleed, additional techniques should be used.

Radionuclide-labeled RBC scans may help localize bleeding sites. A major disadvantage of this test is that it requires active bleeding to detect the source and can localize the bleeding only to a general area of the abdomen. Accuracy rates vary substantially from 24% to 91%. Poor localization is the result of peristaltic and antiperistaltic action moving and dispersing

the radionuclide away from the bleeding site. In a study of 203 patients undergoing RBC scans for lower gastrointestinal bleeding, the scan was positive in 52 cases; however, it incorrectly localized the bleeding site in 13, causing unnecessary surgical procedures in 8 patients.⁶⁶

CT angiography may be useful in localization of active gastrointestinal bleeding.¹⁶ In a review of 124 patients with lower gastrointestinal bleeding, CT angiography demonstrated an accuracy of 100%.⁶⁷ This technique is appealing because of its expediency and wide availability. However, it subjects patients to radiation exposure and risks contrast-induced nephropathy, especially in those patients who require subsequent angiographic therapy.

Angiography is typically reserved for patients in whom endoscopy is not feasible because of severe bleeding with hemodynamic instability or those with persistent or recurrent bleeding and a nondiagnostic colonoscopy. Identification of active bleeding requires bleeding rates of 0.5 to 1 mL/min. Radionuclide-labeled RBC scans may be useful in confirming the presence of active bleeding and in localizing the bleeding site. In the absence of a positive RBC scan, angiography is carried out by first evaluating the superior mesenteric artery, which most often supplies the bleeding site. If the result is negative, the inferior mesenteric and celiac arteries are examined. The success rate of angiography for localizing the bleeding site varies widely from 25% to 70%.⁶⁸ Angiography also offers the ability to treat the bleeding site by delivery of vasoconstrictive agents and therapeutic embolization.

Rarely, patients with exsanguinating bleeding will need urgent surgery. The morbidity and mortality associated with colectomy in the absence of preoperative localization of the bleeding site are higher than in patients who have the bleeding site located preoperatively. Therefore, every effort should be made to locate the bleeding site before surgery.

DIVERTICULAR HEMORRHAGE

Patients with diverticular bleeding typically present with acute blood loss as manifested by maroon-colored stools or hematochezia. Minor or occult bleeding is not characteristic of diverticular bleeding or diverticulosis. Diverticular bleeding and diverticulitis are distinct conditions that rarely occur together. Diverticular bleeding is painless except for the cramping that may occur with the cathartic effect of blood within the colon.

Diverticular bleeding is thought to originate more commonly from the right colon, where ostia tend to be wider and the colon wall thinner. It is estimated that 3% to 5% of patients with diverticulosis will develop diverticular bleeding. Bleeding most commonly occurs during the sixth and seventh decades of life and stops spontaneously in more than 75% of patients. In general, rebleeding occurs in about 15% to 25% of patients.⁶⁹ After a second episode, the risk of rebleeding is approximately 25% to 50%.

Identification of the bleeding diverticulum by colonoscopy may be difficult because diverticula are numerous and bleeding may be intermittent. A definite colonic diverticular bleeding source may be identified in only 21%.⁷⁰ Endoscopic treatment options include submucosal injection of epinephrine, bipolar coagulation, and application of hemoclips and bands. In general, if the bleeding site can be identified endoscopically, treatment is effective with low rebleeding rates.

Figure 125-5 Bleeding colonic diverticulum. A 76-year-old man with acute bleeding from a diverticulum in the cecum. **A.** Angiogram of the ileocolic artery shows brisk bleeding into the cecum from a small terminal branch (arrow). **B.** Distal placement of a microcatheter into the terminal branch with the guidewire advanced 2 cm beyond the microcatheter tip. Note the round outline of the extravasated contrast material indicating hemorrhage into a diverticulum. **C.** Postembolization angiogram shows two metallic coils occluding the bleeding artery. (From McDonald M, Farrell M, Stanson A, et al: Preoperative highly selective catheter localization of occult small-intestinal hemorrhage with methylene blue dye. *Arch Surg* 130:106–108, 1995.)

For ongoing or recurrent bleeding after colonoscopy, angiography often is performed with the intention of identifying an actively bleeding vessel (Fig. 125-5). If the vessel is identified, transcatheter embolization can be attempted, although in some series colonic infarction has been as high as 20%. Transcatheter vasopressin can control bleeding in 90% of cases, but rebleeding rates are high.⁷¹

COLON NEOPLASMS

Colon cancer commonly causes occult lower gastrointestinal bleeding, frequently presenting with a positive result of the fecal occult blood test. It is an uncommon cause of hematochezia and is responsible for 10% of cases of rectal bleeding in patients older than 50 years. Colon neoplasms are discussed elsewhere in the text.

Conclusions

Trauma is the leading cause of death in Americans younger than 45 years and the fifth leading overall cause in the United States.¹ Preliminary data approximate that more than 122,000 people died of traumatic injury in 2011.¹ Trauma has a significant economic burden on U.S. health care, with more than 45 million emergency department visits every year and approximately \$80 billion spent in direct medical costs.^{2,3} It is also the leading cause of disability and exceeds any other disease in productive years lost. In the year 2000, productivity losses due to trauma cost the United States \$326 billion.⁴

Appropriate prompt evaluation of trauma patients is essential to avoid serious morbidity and mortality. Although the physical examination is still vital in the initial assessment of these patients, some studies have shown sensitivity in the range of only 55% to 65% in the setting of blunt abdominal trauma.^{5,6} Furthermore, patients who show no obvious signs of trauma or physical examination findings (such as a seat belt sign, abdominal tenderness, or guarding) may still have significant internal organ injury. Therefore, imaging has come

to play a critically important role in trauma diagnosis and management.

In this chapter, we describe the mechanisms of injury in abdominal trauma as well as the role of imaging modalities—with a focus on computed tomography (CT)—in the evaluation of the trauma patient. We also review CT imaging techniques and the diagnostic criteria used for interpretation in abdominal trauma, with an emphasis on the role of abdominal CT in bowel injury.

Mechanisms of Injury in Abdominal Trauma

Abdominal injury can be divided into blunt and penetrating subtypes. Blunt trauma is the cause of more than 80% of abdominal injuries, whereas penetrating injuries account for approximately 20%.^{7,8} Penetrating injuries include stab and gunshot wounds, with stab wounds being encountered approximately three times more often than gunshot wounds.⁹ Penetrating trauma can have a more straightforward evaluation compared with blunt injury in that the point of wound entry is usually evident, and in the case of gunshot wounds, the exit wound can also be identified. However, the extent of injury with blunt trauma is less conspicuous on physical examination and is thus associated with higher morbidity and mortality.⁶

Most blunt injuries occur after a motor vehicle collision, followed by a pedestrian versus vehicle collision and direct blows to the abdomen by falls, assaults, or sports injuries.^{6,10} Three mechanisms are often used to describe blunt trauma. These are deceleration injuries, crush injuries, and external compression. Rapid deceleration creates significant shearing forces between fixed and mobile parts of organs that can result in lacerations at these areas or at points of attachment to the peritoneum. These forces can also lead to vascular tears or cause stretch injuries to arteries, resulting in infarction of susceptible organs.¹⁰ External objects such as the seat belt or steering wheel can lead to crush injury of the organs between the abdominal wall anteriorly and the thoracic ribs or vertebral column posteriorly.⁹ Finally, a sudden increase in intra-abdominal pressure by external compression can lead to perforation of hollow viscera.

Oftentimes, more than one mechanism occurs during the traumatic incident with simultaneous injury to multiple organs. For instance, an unrestrained driver in a motor vehicle accident who is ejected from the vehicle could initially strike the windshield, producing the first set of injuries, and then could strike the ground outside the vehicle, producing a second set of injuries. If the patient is still moving rapidly, a third or fourth set of injuries may occur until the patient eventually comes to a stop. Injuries may be clustered in one portion of the body, but multiple sites of injury may exist in the same patient. Thus, in

assessing patients with history of trauma, it is helpful to know details of the type of trauma as this can be useful in determining specific patterns of injured organs. In addition, the mechanism of injury has been found to be an independent predictor for mortality and long-term functional impairment.⁷

The spleen is the most commonly injured intra-abdominal organ and may be the only affected organ in up to 60% of cases.⁷ Following the spleen, in order of decreasing frequency, the other commonly injured organs are the liver, kidneys, small bowel or mesentery, bladder, colon or rectum, diaphragm, pancreas, and major vessels.¹⁰

Diagnostic Techniques in Patients with Abdominal Trauma

The diagnostic approach to trauma patients varies according to their hemodynamic status. Patients who remain hemodynamically unstable despite appropriate resuscitation efforts are usually taken to the operating room for emergent laparotomy because of high suspicion of ongoing hemorrhage. Diagnostic techniques for abdominal trauma include the focused assessment with sonography for trauma (FAST) and diagnostic peritoneal lavage. In short, FAST is used to evaluate for free intraperitoneal fluid and is usually performed before exploratory laparotomy. It is a rapid, noninvasive test that can be performed at the bedside and has been shown to have up to 90% specificity for blood products in the abdomen and pelvis.¹¹ However, it is an operator-dependent examination that does not focus on direct signs of organ trauma. It also has a low sensitivity (29%-35%) for organ injury in the absence of hemoperitoneum.¹¹ Because intra-abdominal injury cannot be ruled out with normal findings on FAST scan, further diagnostic testing, such as diagnostic peritoneal lavage or CT, is often necessary.

Diagnostic peritoneal lavage is used to evaluate for intra-abdominal hemorrhage and hollow organ injury. Its use has markedly decreased because of advances in imaging technology and increased nonoperative management after trauma. The principle of this technique is to infuse saline into the peritoneum to mix with possible blood and then to recover the fluid for analysis. Diagnostic peritoneal lavage has high sensitivity in the detection of peritoneal bleeding, and some trauma surgeons appreciate its capacity of providing them prompt and easy-to-interpret information in settings in which radiologists are not readily available to interpret films.¹² However, its disadvantages include lack of specificity for the source of bleeding and that it is an invasive procedure with associated risks and morbidity.^{13,14}

Computed Tomography Use in Abdominal Trauma

The speed and accuracy of CT as well as its widespread availability in emergency departments and trauma centers have led this imaging modality to play a principal role in the triage and diagnosis of trauma patients. Although the use of CT in abdominal trauma dates to the 1980s,¹⁵ the advent of helical scanning and multidetector helical computed tomography (MDCT) has allowed it to be more widely used with reduced scan times and improved image quality.

In the past, trauma patients were initially evaluated with conventional chest, cervical spine, and pelvic radiographs. CT scans were obtained only for hemodynamically stable patients with blunt abdominal trauma, in those with no evidence of penetrating injury, or in those who presented obtunded. Today, CT is more frequently used in patients with some degree of clinical instability, provided they respond to initial resuscitation and are stable enough to undergo CT. In fact, a study published in 2009 found that of patients who underwent whole-body CT, one of every five had been in shock at the scene of the trauma and one of six at the time of admission.¹⁶ CT is now also routinely used in patients with chest injuries or penetrating wounds.

When it comes to clinical decision making, CT scanning has proved to be superior to other methods in the diagnosis of injuries that require surgical intervention. In a study conducted by Deunk and coworkers,¹⁷ researchers found that MDCT findings after trauma often result in a change in treatment decisions. Moreover, increased CT use after trauma has led to a shift to nonoperative management and decreased morbidity and in-hospital mortality. A large number of injuries involving the liver, spleen, and kidneys are now managed conservatively if patients are hemodynamically stable.

Computed Tomography Imaging Techniques and Interpretation

Trauma CT protocols should attempt to optimize images to help radiologists detect injuries while minimizing risks to the patient. To achieve this goal, it is important to consider various aspects of image acquisition and analysis. These include the use of contrast material, different phases of acquisition with their varying degrees of contrast enhancement, radiation dose, and image processing.

CONTRAST MATERIAL

The intravenous use of contrast material improves the sensitivity and specificity of CT for detection of injury. The American College of Radiology developed the Appropriateness Criteria, which are evidence-based guidelines meant to aid in the selection of imaging and routes of administration of contrast material in different emergency scenarios. The guidelines state that the intravenous use of contrast material is critical to identify bowel, visceral, or vascular injury in the setting of blunt abdominal trauma.¹⁸ In addition, they recommend against the use of oral contrast material in the setting of blunt abdominal injury, probably because of lack of additional diagnostic value as well as potential delay in obtaining the CT images owing to wait time for enteric contrast material to progress.¹⁹

One of the more controversial issues surrounding the intravenous use of contrast material is the risk of acute kidney injury, especially in the elderly, those with established renal insufficiency, and patients with chronic diseases, such as diabetes mellitus, congestive heart failure, and hypertension. This is especially worrisome in the setting of trauma, when oftentimes one cannot obtain a thorough history and testing for renal function might delay possible treatment.

Some centers have recently been looking at point-of-care (POC) creatinine testing in patients presenting for imaging with nonspecific history that could be concerning for kidney disease.²⁰ A study by Lee-Lewandrowski and colleagues²¹ looked

at POC creatinine testing and its impact on clinical operations in the radiology department of a large academic medical center. This group found that 5.3% of patients (441 per month) who presented for scans did not have a recent creatinine level or estimated glomerular filtration rate; 26% of these were determined to be abnormal. They also found good agreement between POC and central laboratory plasma creatinine testing; however, the POC creatinine testing was approximately 47% more expensive than central laboratory plasma creatinine testing. However, because of the increased timeliness and improved quality of scans with intravenous contrast material, the authors suggested that POC creatinine testing improves clinical operations and is likely to be cost-effective.²¹ A study of POC creatinine testing in the emergency department also showed good correlation between POC and serum testing, leading the authors to conclude that because of its ease of use and rapid turnaround time, it could be of substantial benefit in the emergent setting.²²

MULTIPHASIC IMAGING

Because of increased image acquisition speed, it is possible to achieve multiphasic imaging with a single bolus of contrast material. However, there is no current consensus on the optimal number of phases needed for a trauma protocol as peak contrast enhancement varies between organs and there are advantages to each of the phases. Some researchers believe that the portal venous phase, which occurs 65 to 80 seconds after initiation of administration of the contrast material, is a good compromise in the diagnosis of parenchymal injury.¹⁰ In a study of the role of multiphasic imaging in pancreatic injury detection, for instance, researchers found that the portal venous phase was the most accurate to determine signs suggestive of ductal injuries.²³ Results of a study on splenic trauma by Boscak and associates²⁴ showed that the portal venous phase was more sensitive than the arterial phase in the diagnosis of parenchymal injury and active hemorrhage, yet the arterial phase was more sensitive for pseudoaneurysm detection. The authors suggested that dual phase imaging offers optimal overall performance.

Multiphasic imaging is also beneficial in trying to further characterize vascular injuries. Acquiring images at different points in time helps differentiate between contained injury and active vascular hemorrhage as well as distinguish arterial from venous sources.²⁵ By using delayed imaging, one can theoretically characterize the rate of bleed by looking for enlarged areas of extravasation of contrast material²⁶ as well as evaluate the collecting system of the kidneys.

RADIATION DOSE

With regard to radiation dose, as with all imaging, a risk-benefit analysis needs to be performed for each patient to determine if CT is appropriate. Specifically, the risks of radiation and intravenous administration of contrast material must be weighed against the benefits from diagnosis of traumatic injuries. In light of the fact that CT is superior to clinical evaluation and modalities such as diagnostic peritoneal lavage for diagnosis of clinically significant abdominal injuries,^{27,28} CT is a mainstay in the imaging of acute traumatic injury. It is critical to adhere to the concept of ALARA (as low as reasonably achievable) in performing CT; that is, image quality should be maximized but not at the expense of increased radiation dose to the patient.¹⁰

As such, there are multiple dose reduction tools available on current CT scanner platforms, including automatic tube current modulation, which allows the tube current to automatically change with the region of the body being imaged,²⁹ thereby lowering radiation dose.³⁰ In addition, whereas most CT is reconstructed with conventional filtered back projection, new research is focused on a host of new iterative reconstruction algorithms designed to reduce dose while maintaining image quality.³¹⁻³⁷ Willemink and associates³⁸ recently showed that although the mean time required for CT image reconstruction for whole-body trauma CT is statistically significantly higher with iterative reconstruction as opposed to filtered back projection, this difference is on the order of 45 seconds, likely making this a clinically insignificant delay in the trauma setting. This study was limited in that it was performed with one CT vendor's software only; additional studies with the other major vendor's iterative reconstruction products are likely needed to assess whether this holds true for other iterative reconstruction algorithms.

IMAGE PROCESSING

Current multidetector CT platforms have the ability to acquire data at submillimeter section thickness with isotropic data sets. Interpretation of these submillimeter-thick data sets can be cumbersome, and most centers will reconstruct these images at 2.5- or 5.0-mm section thickness to facilitate image interpretation.¹⁰

In addition, reconstruction of axial data sets in the coronal and sagittal planes can often be performed by the CT technologist at the console and sent to a picture and archiving communication system for interpretation by the radiologist in conjunction with the axial data sets. Coronal and sagittal reconstructions have the ability to help confirm diagnoses made on axial images as well as to aid in diagnosis of injuries of other structures, such as the bladder, diaphragm, and spine (Fig. 126-1).³⁹⁻⁴³

Approach to Computed Tomography Interpretation

The mechanisms of traumatic injuries are often complex and can lead to multiorgan injury. As such, a consistent and repeatable search pattern can help minimize missed injuries. The use of a rigorous routine in the interpretation of trauma patient CT studies significantly diminishes the number of missed traumatic lesions, especially in the setting of multiple injuries.^{44,45} As with any CT interpretation, the specific search pattern used is less important than simply having and following a comprehensive search pattern in each case.

Computed Tomography Findings in Abdominal Injury

LIVER AND SPLEEN

Currently, most splenic and liver injuries are managed conservatively in the hemodynamically stable patient. The major types of blunt hepatic and splenic trauma include subcapsular and intraparenchymal hematomas (Fig. 126-2), lacerations (Fig. 126-3), active hemorrhage, and other vascular injuries.^{46,47} Of

Figure 126-1 Left diaphragmatic rupture. A 55-year-old man who was driving a motorcycle and was struck by a motor vehicle. **A.** Axial image of a contrast-enhanced CT scan reveals the majority of the stomach in the thorax just lateral to the heart, indicating diaphragmatic rupture (arrow). **B.** Coronal reformatted image again shows the stomach herniating into the thorax and a ruptured diaphragm (curved arrow). The patient was taken to the operating room, where his 12-cm left diaphragmatic rupture was repaired. This case illustrates the value of coronal reformatted images in the acute traumatic setting.

Figure 126-2 Subcapsular hematoma. A 55-year-old man was evaluated after blunt abdominal trauma. Contrast-enhanced CT scan of the abdomen reveals a subcapsular hematoma on the right hepatic lobe (arrowheads). Note the differing densities of the contents that indicate this is a hematoma, with more dense blood products along the gravity-dependent aspects of the hematoma (arrow).

Figure 126-3 Splenic injury with active extravasation. A 45-year-old woman who was involved in a motor vehicle collision. Contrast-enhanced CT of the abdomen reveals a splenic injury with hemorrhage adjacent to the spleen (curved arrow) and an area of active extravasation (straight arrow). Splenic injury with active bleeding was confirmed at exploratory laparotomy with subsequent splenectomy.

note, vascular injury can be subtle, and its only sign may be end-organ damage. The American Association for the Surgery of Trauma (AAST) has devised injury grading scales for both liver and splenic injuries (Tables 126-1 and 126-2).

PANCREAS

In the pancreas, two thirds of injuries occur in the body of the organ; the rest occur equally in the head, neck, and tail (Fig. 126-4). In addition, pancreatic injuries are rarely isolated; it is estimated that 70% to 90% of injuries to the pancreas are

accompanied by injuries to other organs.⁴⁸ The AAST grading scale for pancreatic injury is based on the location of injury as well as on the degree of parenchymal and ductal destruction (Table 126-3).

Hepatic, pancreatic, and splenic injuries are further discussed in Chapters 91, 99, and 106, respectively.

KIDNEYS

CT is the imaging modality of choice to evaluate for renal injury after trauma because of its ability to accurately depict the renal

parenchyma, collecting system, and blood vessels.⁴⁹ Renal injury can be found in approximately 8% to 10% of abdominal traumas, although 80% to 90% of injuries result from blunt rather than from penetrating trauma.^{49,50} Trauma to the kidneys can result in contusion, laceration, hemorrhage, or avulsion of the renal pedicle (Fig. 126-5). Gross hematuria after trauma should prompt evaluation of the renal system, although the absence of this finding does not exclude injury.^{49,50}

Early and delayed imaging is necessary to fully evaluate the urinary system as delayed images are essential to determine the integrity of the collecting system.^{10,49,50} The AAST has devised an injury grading scale based on depth of injury as well as involvement of renal vasculature and the collecting system

(Table 126-4). Grade I injuries account for approximately 75% to 80% of traumatic injuries, whereas grade II injuries account for 10%.⁴⁹ Thus, as is the trend with other organs, most renal injuries are managed conservatively.

In addition to routine MDCT, CT cystography is recommended in patients who present with gross hematuria and a pelvic fracture to search for serious bladder injury. Most bladder ruptures (85%-100%) are manifested with pelvic fractures, yet only 6% to 8% of patients with pelvic fractures due to trauma present with a ruptured bladder (Fig. 126-6).⁵¹ The location of rupture is important for management decisions as most cases of extraperitoneal rupture can be managed conservatively with drainage (Fig. 126-7), whereas intraperitoneal ruptures

TABLE 126-1	American Association for the Surgery of Trauma Liver Injury Scale	
Grade*	Lesion	Injury Description
I	Hematoma	Subcapsular, <10% surface area
II	Laceration	Capsular tear, <1 cm parenchymal depth
	Hematoma	Subcapsular, 10% to 50% surface area
III	Laceration	Intraparenchymal, <10 cm in diameter
		Capsular tear, active bleeding
IV		1-3 cm parenchymal depth, <10 cm in length
		Subcapsular, >50% surface area or ruptured with active bleeding
V		Intraparenchymal hematoma >10 cm or expanding
	Laceration	>3 cm parenchymal depth
VI	Laceration	Parenchymal disruption involving 25% to 75% of hepatic lobe or 1-3 Couinaud segments within a single lobe
		Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
V	Vascular	Juxtahepatic venous injuries (i.e., retrohepatic vena cava and/or central major hepatic veins)
	Vascular	Hepatic avulsion

TABLE 126-2	American Association for the Surgery of Trauma Splenic Injury Scale	
Grade*	Lesion	Injury Description
I	Hematoma	Subcapsular, <10% surface area
II	Laceration	Capsular tear, <1 cm parenchymal depth
	Hematoma	Subcapsular, 10% to 50% surface area
III	Laceration	Intraparenchymal, <5 cm in diameter
		Capsular tear, active bleeding
IV		1-3 cm parenchymal depth, does not involve trabecular vessels
		Subcapsular, >50% surface area or expanding
V		Ruptured subcapsular or intraparenchymal hematoma
		Intraparenchymal hematoma >5 cm or expanding
V	Laceration	>3 cm parenchymal depth or involves trabecular vessels
	Laceration	Involves segmental or hilar vessels, producing major devascularization (>25% of spleen)
V	Vascular	Completely shattered spleen
	Vascular	Hilar vascular injury that devascularized the spleen

From Moore EE, Cogbill TH, Jurkovich GJ, et al: Organ injury scaling: Spleen and liver (1994 revision). *J Trauma* 38:323-324, 1995.
*Advance one grade (up to grade III) for multiple injuries.

Figure 126-4 Pancreatic transection with retroperitoneal and intraperitoneal hemorrhage. A 42-year-old woman after a bicycle accident in which she suddenly braked and fell over the handlebars onto the pavement. **A.** Contrast-enhanced CT reveals a large amount of retroperitoneal and intraperitoneal hemorrhage (straight arrows). The pancreatic tail is deviated anteriorly by the hemorrhage (curved arrow). **B.** A portion of the transected pancreatic tail is seen in its expected location in the left upper quadrant (arrowhead). The diagnosis of pancreatic transection was confirmed at exploratory laparotomy, at which distal pancreatectomy and splenectomy were performed.

(Fig. 126-8) usually require surgical intervention for repair.⁵² Other findings of bladder trauma include contusions and interstitial injury, which are managed conservatively, and combined rupture, which usually requires repair.⁵³

Computed Tomography and Bowel Injury

Studies have historically shown that bowel injury occurs in approximately 1% to 5% of abdominal trauma patients. In a

more recent study of patients after blunt abdominal trauma, 9% were found to have hollow viscus injury. One third of these (approximately 3%) were in the stomach and the rest in the bowel.⁵⁴ The detection of a bowel injury in a blunt trauma patient can be difficult because clinical signs are often

TABLE 126-3 American Association for the Surgery of Trauma Pancreatic Injury Scale

Grade*	Lesion	Injury Description
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury or tissue loss
	Laceration	Major laceration without duct injury or tissue loss
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal [†] transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

*Advance one grade (up to grade III) for multiple injuries.

[†]Proximal pancreas is to the patient's right of the superior mesenteric vein.

Figure 126-5 Splenic laceration and renal injury secondary to gunshot wound. A 23-year-old pregnant woman after a gunshot wound to the left upper abdomen. Contrast-enhanced CT of the abdomen and pelvis reveals a splenic laceration (straight arrow). Note the extensive hemorrhage and gas inside the left renal fossa (arrowhead) and the left renal parenchymal injury (curved arrow). The patient underwent an exploratory laparotomy and splenectomy. Intraoperative evaluation of the left kidney revealed renal laceration and collecting system injury.

TABLE 126-4 American Association for the Surgery of Trauma Kidney Injury Scale

Grade*	Lesion	Injury Description
I	Contusion	Microscopic or gross hematuria, urologic studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
	Laceration	<1.0 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	<1.0 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through renal cortex, medulla, and collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum which devascularizes kidney

From Moore EE, Shackford SR, Pachter HL, et al: Organ injury scaling: Spleen, liver, and kidney. *J Trauma Acute Care Surg* 29:1664, 1989.

*Advance one grade (up to grade III) for multiple injuries.

Figure 126-6 Pelvic trauma with normal findings on CT cystography. A 45-year-old man is evaluated after a motor vehicle collision. CT of the pelvis revealed multiple pelvic fractures and pelvic hemorrhage (left anterior acetabular fracture is denoted by the straight arrow). The patient underwent CT cystography, revealing smooth contour of the urinary bladder wall (arrowheads) and no evidence of bladder injury.

Figure 126-7 Extraperitoneal bladder rupture. A 51-year-old woman after a motorcycle accident. **A.** Coronal reformatted CT scan of the abdomen and pelvis revealed extensive pelvic fractures with pelvic hemorrhage. A decompressed urinary bladder with a Foley catheter contains contrast material from initial intravenous injection (*between straight arrows*). **B.** Coronal reformatted image of the abdomen and pelvis viewed on bone windows shows some of the representative pelvic fractures (*arrowheads*). **C.** Because of the extensive pelvic trauma, the patient underwent CT cystography, revealing an appropriately distended urinary bladder (*curved arrow*) as well as extravasated contrast material anterior and lateral to the bladder (*straight arrows*). These findings are compatible with an extraperitoneal bladder rupture.

Figure 126-8 Intraperitoneal bladder rupture. A 33-year-old woman after penetrating pelvic injury. **A.** Contrast-enhanced CT scan reveals hematoma and air in the pelvis bilaterally (*straight white arrows*). A partially decompressed urinary bladder is seen containing a Foley catheter (*curved arrow*). **B.** Because of extensive hemorrhage in the pelvis, CT cystography was performed, and coronal reformatted images reveal extravasated contrast outlining bowel loops in the intraperitoneal space (*straight white arrows*). Note the approximate site of rupture at the left lateral bladder wall (*curved arrow*). Notice is made of an enlarged postpartum uterus in the central part of the image (*arrowhead*).

nonspecific or delayed in presentation. Moreover, in patients with polytrauma, subtle findings of a bowel injury can be overlooked in the presence of other organ injuries, especially if there is no evidence of extraluminal gas. The goal of diagnosis is to determine which patients require surgical intervention and which can be managed nonoperatively.

With the increasing number of patients who are managed conservatively, prompt accurate diagnosis is essential to minimize morbidity and mortality.¹⁰ Studies have shown that delay

in intervention because of delay in diagnosis leads to increased morbidity and mortality. One study showed that delays as short as 8 hours were more likely to result in sepsis, peritonitis, and death in patients who underwent laparotomies, whereas another demonstrated that delays longer than 24 hours could lead to acute respiratory distress syndrome and sepsis in patients with hollow viscus injury.^{55,56} A more recent study showed that morbidity increased threefold with a 5-hour delay between admission and laparotomies.⁵⁷

The sensitivity and specificity of CT in the evaluation of bowel injuries vary in the literature. Cited sensitivities range from 64% to 95%, and specificities are between 92% and 100%.^{10,58-61} Atri and colleagues⁶² also cited a high negative predictive value of CT with a less than 1% post-test probability of injury with normal findings on CT scan. Reasons for missed diagnosis include major injury to other organs causing readers to overlook minor bowel trauma, patient body habitus, support and monitoring devices that can cause artifact, and absence of extraluminal gas.⁴⁴ Thus, it is imperative that readers establish a specific search pattern while reading images to minimize false-negative readings.

Computed Tomography Findings in Bowel and Mesenteric Injury

Injury to the bowel and mesentery can have a range of appearances on CT from a small mesenteric hematoma with no direct evidence of bowel damage to a complete transmural rupture of bowel wall. More specifically, the mucosal surface of the bowel wall can be torn with an intact serosal surface, there can be bleeding into the bowel wall with intact mucosal and serosal layers, or there can be edema in the bowel wall representing bowel contusion. Alternatively, the serosal surface of the bowel may be injured, producing a hematoma adjacent to the bowel without frank perforation. The mesentery can also be injured by disruption of the arterial supply or venous drainage or by a hematoma from capillary injury. Alternatively, a segment of the mesentery can be avulsed, with its vessels and fat separated from the remainder of the mesentery.

Small bowel injuries occur twice as frequently as colonic injuries because the small bowel is more mobile. The proximal jejunum and distal ileum are particularly susceptible to blunt injury as shearing forces that result from this type of trauma

often affect the mobile loops associated with fixed points.⁶³ The transverse colon is the most vulnerable portion of the large bowel because of its exposed location, whereas the ascending and descending colon are relatively fixed in the retroperitoneum and are less susceptible. In terms of penetrating trauma, the small bowel⁶ and colon are two of the most commonly injured organs because of firearms. The liver, small bowel, and colon are the three most commonly injured organs from injuries inflicted by knives.⁶⁴

There are various CT findings that are helpful in the diagnosis of clinically important bowel and mesenteric injury. Unfortunately, these findings are not uniformly present in patients with bowel injury and therefore vary in sensitivity and specificity.¹⁰ It is important to look for these signs carefully as the presence of several findings might increase the likelihood of significant injury. The CT signs with highest specificity include bowel wall discontinuity, extraluminal contrast material, and free air. Other, less specific but more sensitive signs include focal wall thickening, abnormal bowel wall enhancement, mesenteric stranding, and free intraperitoneal fluid.⁶³

BOWEL WALL DISCONTINUITY

Focal wall discontinuity is 100% specific for bowel injury, and the most severe bowel injuries—frank perforations—usually are manifested with this sign (Fig. 126-9). Nonetheless, only 7% of injuries present with this finding, resulting in a low sensitivity.⁶⁵ The size of the perforation defect is usually small, which also contributes to the infrequency of the finding.⁶⁶

EXTRAVASATION OF ORAL CONTRAST MATERIAL

Many institutions do not administer oral contrast material on a routine basis for trauma CT because of potential delay in

Figure 126-9 Colonic perforation from stab wound. A 65-year-old man presented with a stab wound to his left flank. **A.** Axial CT scan of the abdomen and pelvis reveals free intraperitoneal air (*straight arrows*) with discontinuity of the descending colonic wall, compatible with traumatic colonic perforation. Note is also made of a hematoma within the left flank musculature at the site of the stab wound (*curved arrow*). **B.** Coronal reconstruction of the CT image again reveals free intraperitoneal air (*straight arrows*) and left flank musculature hematoma (*curved arrow*). Incidental note is also made of an abdominal aortic aneurysm.

scanning from time required to get contrast material through the bowel. Thus, even though extravasation of oral contrast material is a specific sign⁶³ for bowel perforation, it is uncommonly seen.

EXTRALUMINAL AIR

Detection of extraluminal gas on CT after bowel injury has been reported over a wide range of 20% to 75% of cases.⁶³ Free air in the peritoneal or retroperitoneal cavity is relatively specific for injury, but the amount of free air may be low, thereby making detection more challenging. For instance, a loop of bowel may be fluid filled when it is ruptured with no initial release of gas into the peritoneum; the perforation can be self-contained by sealing spontaneously; or injury can lead to development of an ileus, which prevents air from being pushed down the intestine.⁶³ Lung and bone windows are often used to optimize detection of extraluminal air.

Pneumoperitoneum secondary to bowel rupture usually accumulates behind the anterior abdominal wall (see Fig. 126-9), below the diaphragm, or along the peritoneal surfaces of the liver and spleen. Air might also be seen in the porta hepatis, mesentery, mesenteric veins, or portal vein.⁶⁶ Detection of extraluminal gas is not 100% specific for bowel injury and can be caused by other factors. These include penetrating injuries (which introduce external air into the body), mechanical ventilation, bladder rupture with Foley catheter, barotrauma, pneumothorax, and peritoneal lavage before CT.^{63,66} Air contained between the inner layer of the abdominal wall and the parietal peritoneum, known as pseudopneumoperitoneum, can also lead to a false-positive bowel injury diagnosis.⁵⁹ Thus, free air can increase the probability of bowel injury when it is found in association with other signs; but if it is an isolated finding, other causes could be considered.

FOCAL BOWEL WALL THICKENING

With appropriate bowel distention, normal bowel wall thickness should not exceed 3 mm. Localized thickening of the bowel wall can be a clinically important sign and is found in approximately 45% to 75% of bowel injuries.^{44,62,66} In the absence of other findings, such as free fluid in the pelvis or stranding or fluid in the adjacent mesentery, focal bowel thickening is less likely to require surgical intervention.^{10,66} In other words, an isolated, focal finding of thickened bowel after trauma could be secondary to peristalsis or a focal bowel wall contusion that might not require operative management.⁵⁹

Compared with localized injuries as a direct result of trauma, generalized bowel wall thickening can be a sign of hypoperfusion or “shock bowel.”¹⁰ Other signs of decreased volume status, known as the hypoperfusion complex, include a flattened inferior vena cava, a narrowed aorta, and increased enhancement of the adrenal glands, kidneys, and bowel (Fig. 126-10).⁶⁷ Volume overload, usually secondary to overhydration with intravenous fluids, can also lead to diffuse wall thickening in the absence of all other findings of the hypoperfusion complex.⁵⁹

ABNORMAL BOWEL WALL ENHANCEMENT

Abnormal bowel wall enhancement can result from either hypoperfusion or local vascular injury, which can lead to increased vascular permeability and leakage of contrast material

into the interstitium.^{44,68} Several studies suggest that irregular increased enhancement after administration of contrast material is often a sign of full-thickness injury.^{63,69} On the other hand, decreased enhancement of the bowel wall can be a sign of ischemia.⁵⁹ Reference points often used to evaluate abnormal enhancement include nearby blood vessels and adjacent bowel loops.⁶⁸

MESENTERIC INJURY

Mesenteric injuries include mesenteric infiltration (also known as stranding), hematomas, and beading or abrupt termination of vessels.⁵⁹ Mesenteric stranding is often a sign of mesenteric injury and can be present with or without accompanying bowel injury (Fig. 126-11). This finding, when it is present with focal bowel thickening, likely represents a clinically important injury.^{44,59} However, it can also represent isolated mesenteric damage and thus has a low specificity for bowel injury.⁶³ For instance, a localized mesenteric hematoma without any other signs or findings indicative of bowel injury suggests an isolated injury of a mesenteric vessel.⁴⁴

Mesenteric hematomas are often triangular when small, but they may be rounded or oval when larger. In the presence of a larger hematoma, it is often important to look at delayed phase imaging to assess whether there is active bleeding that requires emergent surgery to prevent ischemic bowel. An irregular pattern, or beading, of mesenteric vessels and the abrupt termination of mesenteric arteries or veins are also signs of vascular injury that could require intervention (Fig. 126-12).⁵⁹

FREE INTRAPERITONEAL FLUID

Intraperitoneal fluid detection is a highly sensitive (90%-100%) but nonspecific (10%-15%) finding for bowel injury as peritoneal fluid may have a traumatic or nontraumatic origin.^{10,70} Sources of traumatic intraperitoneal fluid include blood from a solid organ, bowel, or mesenteric injury; bile from a ruptured gallbladder or bile duct; and urine from a ruptured bladder. Nontraumatic causes of fluid include ascites from a comorbid condition such as cirrhosis and physiologic fluid in the pelvis of women of childbearing age, among others.

The location of intraperitoneal fluid can often lead to the correct diagnosis.^{63,71} If fluid is seen only adjacent to bowel or caught between the leaves of the mesentery, it likely results from a bowel injury. If it is seen throughout the abdomen including upper and lower peritoneal compartments as well as the pelvis and a large amount of blood is present, the injury is more likely in a solid organ, such as a splenic or hepatic laceration. Upper abdominal solid organ injuries initially bleed into the major peritoneal space adjacent to the organ, and blood then migrates in an anatomic pathway down the paracolic gutters to the pelvis (Fig. 126-13).^{26,63} Thus, if a patient demonstrates blood caught between the leaves of the mesentery and does not have blood in the paracolic gutters or in the pelvis, the source of bleeding is likely bowel.

The density of intra-abdominal fluid in a trauma patient can also help identify the site of bleeding. Clotted blood is denser than serous blood, which is denser than urine or bile. The sentinel clot, which is usually found adjacent to the bleeding site, can be recognized on CT by its higher attenuation (45-70 HU), whereas unclotted blood found farther from the source has lower attenuation (30-45 HU).⁷² However, attenuation can be

Figure 126-10 Active extravasation from the superior mesenteric artery with signs of hypoperfusion and shock. A 50-year-old man who was a restrained driver in a motor vehicle collision. **A.** Contrast-enhanced CT reveals a large amount of intraperitoneal hemorrhage (*curved arrows*) with some adjacent thickened loops of small bowel in the left lower quadrant. The inferior vena cava is narrowed and slitlike (*arrowhead*), indicating a hypovolemic state. **B.** Pooling of intravenous contrast material at the base of the mesentery (*straight arrow*), compatible with active extravasation. Note again the presence of intraperitoneal hemorrhage (*curved arrow*) and a narrowed inferior vena cava (*arrowhead*). **C.** Sagittal reformatted image again reveals pooling of extravasated intravenous contrast material at the base of the mesentery (*straight arrow*), likely from a branch of the superior mesenteric artery (*curved arrow*). These findings were confirmed at diagnostic angiography as well as at subsequent exploratory laparotomy.

Figure 126-11 Mesenteric hematoma. An 80-year-old man after a motor vehicle collision with a tree. Contrast-enhanced CT of the abdomen and pelvis revealed fat stranding and induration within the right lower quadrant mesentery (*arrows*) adjacent to the ascending colon. Findings were compatible with colonic contusion and mesenteric hematoma.

Figure 126-12 Traumatic abdominal hernia and active extravasation of intravenous contrast material. **A.** A 41-year-old man is evaluated after a motor vehicle collision. Contrast-enhanced CT of the abdomen and pelvis revealed traumatic left abdominal wall hernia (curved arrows) with hemoperitoneum (arrowheads) and active extravasation in the posterior mesentery in the region of a branch of the inferior mesenteric artery (straight arrow). **B.** Diagram of the midabdomen shows leaves of mesentery forming boundaries of the triangular interloop peritoneal spaces. This is similar to the findings seen in **A** with the mesenteric hemorrhage.

decreased in patients with hemorrhages that occurred more than 48 hours before the scan and in those patients with a low hematocrit.⁷² The density of bile and urine is closer to that of water, and thus their attenuation usually ranges from 0 to 15 HU.

Figure 126-13 Omental laceration. A 56-year-old is evaluated after a motorcycle accident. Contrast-enhanced CT of the abdomen and pelvis revealed hemorrhage and thickening in the region of the omentum in the left upper quadrant (straight arrows). This hemorrhage extended to the splenic flexure of the colon. Additional hemorrhage was identified surrounding the liver (curved arrow). The patient was taken emergently to exploratory laparotomy, which revealed an omental laceration and a partial-thickness tear of the colon at the level of the splenic flexure.

Conclusions

Trauma is the leading cause of death in Americans younger than 45 years and the fifth leading overall cause in the United States. Appropriate prompt evaluation of trauma patients is essential to avoid serious morbidity and mortality. Because of the unreliability of the physical examination and risks from delayed diagnosis, imaging has come to play a critically important role in trauma diagnosis and management.

CT is the primary imaging modality used in the evaluation of patients in the acute traumatic setting because of its speed of acquisition, widespread availability, and high spatial resolution. It can be used after both blunt and penetrating abdominal injuries, and information obtained from CT often guides clinical decision making and treatment planning. Contrast-enhanced CT helps in the diagnosis of solid abdominal organ injury, and its use during the last three decades has led to a paradigm shift from surgical exploration to more conservative management in the hemodynamically stable patient.

Maintaining a consistent scan interpretation pattern is essential for radiologists to avoid “satisfaction of search” as traumatic injuries rarely occur in isolation. This is particularly important in the evaluation of bowel injury as its signs can range from pneumoperitoneum and extravasation of contrast material to more subtle presentations, such as focal bowel wall thickening and adjacent mesenteric hematomas. Radiologists are key members of the trauma team and make a substantial contribution to patient care.

Conclusion

Imaging plays a crucial role in the objective assessment of tumor response to various cancer therapies. Assessment of tumor response serves as an important clinical endpoint in phase II clinical trials and can reasonably predict the overall survival and other clinical events, such as time to progression.^{1,2} More than 70% of recent Food and Drug Administration approvals of oncologic drugs have been based on radiologic response.³ Several response assessment criteria have been used in oncology for assessment of response to gastrointestinal malignant neoplasms. Not only are these for use in research or drug trials, but they may also be incorporated into routine clinical practice. Early detection of therapy resistance may enable individualized treatment approaches tailored to the patient.

World Health Organization and RECIST 1.0 Guidelines

The World Health Organization (WHO) tumor response criteria, published in 1981, recommended the use of the cross product obtained by multiplying the longest diameter in the axial plane and the largest perpendicular diameter.⁴ Treatment response was categorized as complete response, indicating tumor disappearance; partial response, indicating more than 50% decrease in cross product; disease progression, indicating more than 25% increase in cross product; or stable disease, indicating changes that lay between partial response and disease progression. The WHO criteria suggested that in the presence of multiple lesions, the sum of the cross products of individual target lesions may be used to categorize the response. Since their inception, the WHO criteria were widely used for more than two decades.^{5,6} However, their deficiencies became obvious over time. No indication was given of the minimum number of lesions or the minimum size for a lesion to be categorized as a target lesion, and there were no guidelines on what type of

imaging modality may be used. The bidimensional measurements were cumbersome, with minor errors in measurement resulting in a large change to the cross product.⁷ To alleviate these difficulties, several modifications were attempted, but none of these methods was uniformly accepted.⁸

In the year 2000, the Response Evaluation Criteria in Solid Tumors (RECIST) guidelines were published by a task force that included members of the European Organization for Research and Treatment in Oncology, the National Cancer Institute of the United States, and the National Cancer Institute of Canada.⁹ This recommendation was based on a retrospective evaluation of more than 4000 patients in 14 different trials. These guidelines addressed most but not all of the deficiencies in the WHO criteria. RECIST guidelines recommended the use of one-dimensional tumor measurements (the longest diameter) rather than the cross product ([Fig. 127-1](#)). Lesions were categorized as measurable and nonmeasurable; those measuring more than 20 mm on conventional imaging techniques or more than 10 mm on helical computed tomography (CT) were considered measurable. The measurable lesions were categorized as target and nontarget lesions on the basis of the size and reproducibility of measurements. Only target lesions were used for response categorization. The RECIST guidelines recommended that up to 10 target lesions, in up to five organs, may be used in response assessment. The nontarget lesions were not measured unless there was an unequivocal progression of these lesions that indicated progressive disease. As in the WHO criteria, the tumor responses were complete response, indicating the disappearance of all target lesions; partial response, indicating a decrease of more than 30% in the sum of the greatest dimension of target lesions; progressive disease, indicating an increase of more than 20% in the sum of the greatest dimension of target lesions or the appearance of new lesions or unequivocal progression of nontarget lesions; and stable disease as tumors not classified in the other three classes. Major differences between the WHO and RECIST criteria are highlighted in [Table 127-1](#).

Despite the several improvements over WHO guidelines, RECIST 1.0 guidelines did not address many relevant issues, including the measurement of lymph nodes, the utility of newer functional imaging techniques such as positron emission tomography with ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG PET) and perfusion magnetic resonance imaging (MRI), and the assessment in clinical trials using noncytotoxic drugs.^{10,11}

Evolution of RECIST 1.1

In an effort to address these limitations, the RECIST working group made several modifications to the existing criteria after evaluation of prospectively documented data from clinical trials with a total of more than 6500 patients who had more than

Figure 127-1 RECIST 1.0. A 39-year-old man with hepatic metastases from colon cancer. Sum of longest diameter of target lesions on initial scan was 77 mm (A and B). On follow-up CT (C and D), there was progressive disease per RECIST 1.1, with sum of longest diameter of target lesions of 238 mm.

TABLE 127-1 Comparison Between WHO Criteria and RECIST Guidelines		
	WHO	RECIST 1.0
Imaging modality	No particular mention of imaging modality	CT, MRI, and chest radiography are recommended modalities
Definition of measurable lesions	Should be measurable in two dimensions; no limitation on minimal size of the lesion	Should be accurately measurable in at least one dimension; longest diameter >20 mm for nonspiral CT and >10 mm for spiral CT
Method of measurement	Cross product of longest diameter and greatest perpendicular diameter	Longest diameter in axial plane
Number of lesions to be measured	No particular number of lesions specified	Up to total of 10 target lesions (5 per organ) measured
Response evaluation	Complete response: disappearance of all lesions Partial response: 30% decrease in sum of the longest diameters compared with baseline measurements Stable disease: neither partial response nor progressive disease Progressive disease: 20% increase in sum of longest diameters compared with smallest sum of longest diameters, appearance of new lesions, or unequivocal progression of nontarget lesions	Complete response: disappearance of all lesions Partial response: 50% decrease in target lesions, without 25% increase in any one target lesion Stable disease: neither partial response nor progressive disease Progressive disease: 25% increase in size of measurable lesions, appearance of new lesions, or unequivocal progression of nontarget lesions

18,000 target lesions.⁶ Major differences between RECIST 1.1 and RECIST 1.0 are highlighted in Table 127-2.⁶ Modifications in RECIST 1.1 include the following: reduced number of target lesions from a total of 10 per patient (and five per organ) to five per patient (and two per organ); classifying lymph nodes as target lesions and measuring their short axis (not the long axis; the long axis is used for other types of target

lesions); new definitions of how lesions previously determined to be nonmeasurable (e.g., bone lesions) may now be measured (Fig. 127-2); and modifications of guidelines on imaging modalities to be used.^{12,13} As in RECIST 1.0, the tumor lesions are categorized as measurable and nonmeasurable on the basis of their size. A measurable lesion is a lesion with longest axial diameter of more than

10 mm by CT scan (with slice thickness not more than 5 mm) and 20 mm by chest radiography. Lymph nodes greater than 15 mm in short axes are considered measurable (Fig. 127-3). Lesions smaller than 10 mm in longest diameter and lymph nodes with short-axis diameter between 11 and 15 mm are considered nonmeasurable. RECIST 1.1 designates several other lesions nonmeasurable. These include small tumors (nodules with a short-axis dimension <10 mm), leptomeningeal disease, lymphangitic spread, inflammatory breast disease, pericardial/pleural effusions, palpable abdominal masses/organomegaly not reproducible on imaging studies, lesions surrounded by

postradiation scar tissue, and bone metastases without soft tissue masses measuring more than 10 mm. The presence or absence of nonmeasurable lesions should be noted, as unequivocal progression of these lesions indicates progressive disease. As in RECIST 1.0, it is recommended to have baseline documentation of all target and nontarget lesions.

RECIST 1.1 relies on modalities that are reproducible and accurate. For instance, chest CT is preferred to chest radiography; however, if the lesion is clearly defined on a chest radiograph, it may be considered measurable. Overall, CT is considered the most reliable available method for lesion

TABLE
127-2

Comparison Between RECIST 1.0 and RECIST 1.1

	RECIST 1.0	RECIST 1.1
LESION MEASUREMENT		
Minimum size of measurable lesions	CT: 10 mm, spiral; 20 mm, nonspiral	CT: 10 mm; reference to spiral scan deleted
Lymph nodes	Not mentioned	Target lesions >15 mm; nontarget lesions 10-15 mm; nonpathologic <10 mm (short-axis measurements)
Number of lesions to be measured	10 lesions (5 per organ)	5 lesions (2 per organ)
Special considerations on lesion measurability	Cystic lesions; bone lesions considered nonmeasurable	Notes included on measurement of bone lesions, cystic lesions
RESPONSE CRITERIA		
Target lesions	Complete response: lymph node not mentioned Progressive disease: 20% increase over smallest sum on study or new lesions	Complete response: lymph nodes must be <10 mm in short axis Progressive disease: 20% increase over smallest sum on study (including baseline); at least 5-mm increase or new lesions
Nontarget disease	Unequivocal progression considered progressive disease	More detailed description of unequivocal progression; must be representative of overall disease status change, not a single-lesion increase
Overall response	Table with integrated target and nontarget lesions	Two tables, one integrating target and nontarget and the other of nontarget only
Confirmatory measure	For complete response and partial response: criteria must be met again 4 weeks after initial documentation	Retain this requirement <i>only</i> for nonrandomized trials with primary endpoint of response
Progression-free survival	General comments only	More specific comments on use of progression-free survival (or proportion progression free) as phase II endpoint Greater detail on progression-free survival assessment in phase III trials Divided into phase II and phase III Nine categories reduced to 5 In phase III, guidance given about reporting response
Reporting of response results	Nine categories suggested for reporting of phase II results	This section removed; no need to have different criteria for phase II and phase III
Response in phase III trials	More relaxed guidelines if protocol specified	

Figure 127-2 Measurement of bone lesions per RECIST 1.1. Initial (A) and follow-up (B) axial contrast-enhanced CT of the pelvis showed a lytic lesion in the right pubic bone (arrows) with significant interval increase in the soft tissue component on follow-up scan (B) consistent with progressive disease. RECIST1.1, unlike RECIST 1.0, has clear-cut guidelines on measurement of soft tissue components of bone metastases.

Figure 127-3 Measurement of lymph nodes per RECIST 1.1 (arrows). Short-axis measurements are used for lymph nodes in RECIST 1.1 and incorporated with the sum of the longest diameters of other metastatic lesions, if present. Serial axial contrast-enhanced CT images in a 35-year-old man with testicular cancer demonstrated an interaortocaval lymph node that had increased in size from 5 mm in May 2007 (**A**) to 18 mm in April 2008 (**B**), consistent with progressive disease. After chemotherapy, the node demonstrated interval decrease in size to 11 mm in July 2008 (**C**), which was consistent with partial response. In September 2008 (**D**), the node measured 14 mm. This was more than 20% increase in short-axis size but was not considered progressive disease because there also had to be 5 mm of absolute increase in size to qualify for progressive disease. Hence, this was considered stable disease. In December 2008 (**E**), the node measured 4 mm, which was considered a complete response (i.e., nodal size <10 mm).

measurement. Contrast-enhanced MRI may also be used to assess response. Ultrasound, endoscopy, laparoscopy, and tumor markers are considered to be reliably reproducible and not recommended for lesion measurement. PET scan may be helpful in some instances, such as confirming lack of metabolic activity in a site of radiation scar tissue, indicating complete response. New hypermetabolic sites are considered to indicate progressive disease as long as they are confirmed on subsequent CT.

Whereas RECIST 1.1 maintains the four major response categories as in RECIST 1.0, the definition of progressive

disease is modified. In addition to a 20% increase in the sum of diameters of target lesions, an absolute increase of at least 5 mm is required in small lesions. Appearance of new lesions is also considered progression. Inclusion of lymph nodes in RECIST 1.1 needs additional clarifications to avoid confusion. If all lymph nodes have a short axis of less than 10 mm, the result is categorized as complete response. This eliminates the major drawback with RECIST 1.0, whereby normal-sized lymph nodes could not be categorized as complete response.

Figure 127-4 Handling of lesion splitting. Hepatic metastases in a 59-year-old woman with breast cancer. **A.** Initial axial contrast-enhanced CT demonstrated a large hepatic segment V lesion (*straight arrow*). Note splenic metastasis (*curved arrow*). **B.** Post-treatment axial contrast-enhanced CT image demonstrated splitting of the lesion into two smaller lesions (*arrowheads*). The sum of the longest diameter of each individual lesion is used on follow-up scan to assess for changes in tumor size.

Figure 127-5 Pitfalls of RECIST 1.1. A 46-year-old man with poorly differentiated hepatocellular cancer. Axial contrast-enhanced CT images before (**A**) and 1-month after yttrium 90 (^{90}Y) radioembolization therapy (**B**) demonstrated increase in size of the mass (*arrows*), classified as progressive disease. Follow-up CT scans (not shown) revealed favorable response with decrease in tumor size and enhancement. Tumors treated with targeted therapy, including ablation and embolization, may show initial growth because of hemorrhage and edema.

RECIST 1.0 did not have a consensus on how to measure when a lesion splits or when multiple lesions coalesce. In RECIST 1.1, if the lesion splits, the sum of the longest diameters of individual lesions is used and reported as the target lesion sum (Fig. 127-4). If lesions become coalesced and inseparable from one another, the longest diameter of the coalesced lesion is recorded.

Other Tumor Response Assessment Criteria

RECIST 1.1 has limitations, some of which are specific to the tumor subtypes. The two major limitations of RECIST 1.1 are that it solely depends on the anatomic measurements and does not consider the tumor vascularity or parameters of functional imaging. Traditional cancer chemotherapy with cytotoxic agents often resulted in reduction in tumor size. In the last decade, there has been a paradigm shift in the understanding of cytogenetics and molecular biology of neoplasms, with advent of targeted tumor therapies. Several of these new agents are designed to interfere with or to inhibit one or more of the molecular mechanisms of tumor growth and are primarily

cytostatic rather than cytotoxic (Figs. 127-5 and 127-6). Examples of currently used cytostatic agents include antiangiogenic agents (bevacizumab for metastatic colorectal cancers), mammalian target of rapamycin (mTOR) inhibitors (temsirolimus for renal cell cancer), tyrosine kinase inhibitors (imatinib for gastrointestinal stromal tumors), and estrogen blockers (trastuzumab for breast cancer).¹⁴ Studies of several other cancer types, such as prostate cancer, malignant mesothelioma, soft tissue sarcoma, and neuroendocrine tumors, have also shown that RECIST 1.1 criteria are inaccurate in the assessment of response to therapy.

EASL AND MODIFIED RECIST CRITERIA

Forner and colleagues¹² found that RECIST criteria underestimated the tumor response in patients with hepatocellular carcinoma treated with transarterial chemoembolization or radiofrequency ablation. They recommended the use of European Association for the Study of the Liver (EASL) guidelines, which use tumor density measurements in addition to the tumor size for response assessment. These criteria have been successfully used in clinical trials dealing with assessment response to locoregional therapy for hepatocellular cancer.

Figure 127-6 Response to biologic therapy. A 60-year-old woman with metastatic gastrointestinal stromal tumor treated by imatinib mesylate (Gleevec). **A.** Pretreatment (June 2006) contrast-enhanced axial CT showed a large lesion in the right lobe (arrow). **B.** Two months after starting of therapy (August 2006), the lesion (arrow) showed reduction in size but also substantial reduction in central density. **C.** In April 2007, the lesion was still present but completely cystic (straight arrow). This was considered partial response by RECIST 1.1 criteria but would have been considered complete response by Choi criteria. There was new-onset ascites (curved arrow), which was erroneously reported as metastatic tumor. Ascites is often seen because of hypoproteinemia induced by imatinib, and in the absence of solid peritoneal nodules, it should not be considered tumor recurrence. Radiologic error was recognized clinically and the dose of imatinib was reduced. **D.** In December 2009, a mural nodule (arrowhead) within the cystic mass (arrow) was seen, indicating tumor progression, even though total lesion size had not increased. New intratumoral nodules are considered progressive disease in the Choi criteria. This case illustrates many concepts. RECIST 1.1 is not satisfactory in assessing tumor response to biologic agents. Completely cystic hepatic or peritoneal masses after imatinib therapy should not be mistaken for benign cysts or nonviable tumors. Breakthrough clonal proliferation of gastrointestinal stromal tumor may occur after several months of good response to imatinib, especially if the dose is reduced. Ascites is not necessarily an indicator of metastatic peritoneal disease and is more likely secondary to drug effect.

Lencioni and Llovet¹³ proposed a set of modified RECIST (mRECIST) criteria for evaluation of response assessment in hepatocellular cancer. The mRECIST criteria are similar to RECIST criteria except that only the long dimension of the arterially enhancing component of the tumor is used (Fig. 127-7).

CHOI CRITERIA

Choi and associates¹⁵ formulated criteria for assessment of tumor response in gastrointestinal stromal tumors treated with imatinib, incorporating changes in tumor density and tumor size (Table 127-3). Imatinib is a tyrosine kinase inhibitor that primarily acts by inducing tumor apoptosis. On the basis of their study of 173 lesions in patients with advanced gastrointestinal stromal tumor, the authors recommended that a 15% reduction in tumor density or 10% reduction in tumor size should indicate a partial response (Fig. 127-8; see also Fig.

127-6). These criteria had a 97% correlation with ¹⁸F-FDG PET in determining good responders.

MASS CRITERIA

In 2010, Smith and colleagues¹⁶ proposed the morphology, attenuation, size, and structure (MASS) criteria for metastatic renal cell cancer (Table 127-4). Three categories of disease response were proposed: favorable response, intermediate response, and unfavorable response. In their study of 84 metastatic renal cell cancer patients treated with sunitinib or sorafenib, Smith and colleagues found that the accuracy for detection of progression-free survival was higher with MASS criteria (89%) compared with the RECIST criteria (36%) (Fig. 127-9). The authors concluded that time to progression and disease-specific survival differed significantly between the three categories of MASS criteria, indicating that these criteria were able to better differentiate aggressive from nonaggressive disease.

Figure 127-7 mRECIST for hepatocellular cancer. Serial contrast-enhanced CT images in the arterial phase in a 78-year-old man with hepatocellular cancer before (A) and 6 months (B) and 12 months (C) after treatment with TheraSphere (^{90}Y) radioembolization and oral sorafenib demonstrated progressive decrease in the arterially enhancing component. On image C, there was no visible arterially enhancing component. mRECIST criteria for hepatocellular cancer are similar to RECIST criteria except that only arterially enhancing long dimensions (double arrows) are used. This lesion was classified as partial response per RECIST 1.1 and complete response per mRECIST for hepatocellular cancer. Given the lack of change in the lesion during 34-month follow-up, mRECIST was the more accurate predictor in this case.

TABLE 127-3 Choi Response Criteria for Gastrointestinal Stromal Tumors

Complete response	Disappearance of lesions and No new lesions
Partial response	Decrease in size >10% (no new lesions) or Decrease in density >15% (no new lesions)
Progressive disease	New lesions or Increase in size by 10% (but no decrease in density by >15%) or New intratumoral nodules or increase in size of existing intratumoral nodules
Stable disease	None of the above

PERCIST

Two issues to consider in using PET for quantitative tumor assessment are the uniformity of measurement and the reproducibility of results. There have been several previous attempts to standardize PET, including those issued by the European Organization for Research and Treatment of Cancer¹⁷ and the National Cancer Institute.¹⁸ Positron Emission Tomography Response Criteria in Solid Tumors (PERCIST 1.0) represent the most recent effort to create standardized PET criteria.¹⁹ Tumor response is inherently continuous, and discrete categorization, for example, into complete or partial response, may result in the loss of useful data. PERCIST specifies that the percentage of

TABLE 127-4 MASS Criteria for Renal Cell Cancer

Response Type	Definition
Favorable response	No new lesion and any one of the following: Decrease in tumor size >20% One or more predominantly solid enhancing lesions with marked central necrosis or marked decreased attenuation (>40 HU)
Indeterminate response	Does not fit criteria for favorable response or unfavorable response
Unfavorable response	Any of the following: Increase in tumor size of >20% in absence of marked central necrosis or marked decreased attenuation New metastases, marked central fill-in or new enhancement of previously homogeneously hypoattenuating, nonenhancing mass

change in metabolic activity from baseline to post-treatment scans be recorded to provide a continuous plot of tumor activity.

The primary determinant of response with use of PET is the standardized uptake value (SUV), a semiquantitative measure of activity that is most commonly calculated by dividing the measured tumor activity by injected dose/body weight. Among the many variants of SUV, SUV corrected for lean body

Figure 127-8 Choi criteria in gastrointestinal stromal tumor. Axial contrast-enhanced CT images in a patient with metastatic gastrointestinal stromal tumor before (A) and after (B) treatment with imatinib mesylate. Hepatic metastasis (arrows) measured 3.2 cm with attenuation of 145 HU on initial scan (A) and 3.0 cm with attenuation of 84 HU on follow-up scan (B). These findings were considered stable disease according to RECIST 1.1 and partial response according to Choi criteria.

Figure 127-9 MASS criteria. A 52-year-old man with metastatic papillary renal cell cancer treated with sunitinib. Pretreatment (A) and post-treatment (B) images demonstrated mild increase in size of the posterior lesion (arrows) and significant decrease in attenuation/enhancement. Anterior lesion (arrowheads) showed reduction in size and density. This was consistent with favorable response per MASS criteria.

mass (SUL) was selected for use with PERCIST because this parameter has been shown to be less susceptible to variations in the patient’s body weight than the other SUV metrics.^{20,21} The SUL peak is obtained on the single most active lesion on each scan. This peak is defined as the average activity within a spherical region of interest measuring 1.2 cm in diameter (equivalent to a volume of 1 cm³) centered on the most metabolic portion of the tumor. The SUL peak may be located in a different lesion on a follow-up scan. By use of the same concept as RECIST, PERCIST recommends that the sum of the activity of up to five target lesions (up to two per organ) be used as a secondary determinant of response. As an additional metrics to SUL, PERCIST also suggests the measurement of total lesion glycolysis (TLG), so that the value of TLG may be evaluated. TLG is a measure of the FDG uptake of the entire tumor above a preset threshold and is calculated by multiplying the mean SUV by total tumor volume (in milliliters).²² PERCIST provides four response categories as shown in Table 127-5 (Figs. 127-10 and 127-11).

TABLE 127-5 PERCIST 1.0	
Response Type	Definition
Complete response	Disappearance of all FDG-avid lesions
Partial response	>30% reduction and at least 0.8 SUL mean unit reduction in most avid lesion
Progressive disease	>30% increase and at least 0.8 SUL mean unit increase in most avid lesion
Stable disease	New FDG-avid lesion None of the above

PET has also been incorporated in the revised International Working Group criteria for assessing treatment response of lymphoma. These are a complex set of criteria that use CT, PET, and bone marrow biopsy.²³⁻²⁵ Because this classification system does not deal with gastrointestinal cancers, they are not dealt with further in this chapter.

Figure 127-10 PERCIST criteria. Pretreatment (**A**) and post-treatment (**B**) PET/CT image sets in a 59-year-old man with pancreatic cancer demonstrated stable tumor sizes on CT (arrowheads). However, there was 41% decrease in SUL, indicating that tumor (arrows) has responded (partial response). PERCIST compares the metabolically most active lesion as measured with SUL peak.

Figure 127-11 PERCIST criteria. A 53-year-old with colorectal cancer metastases undergoing combined chemotherapy with gemcitabine and irinotecan. Pretreatment (**A**) and post-treatment (**B**) PET/CT image sets showed 50% decrease in SUL in previously seen hepatic metastasis (arrowheads). However, a new hypermetabolic retroperitoneal lesion (arrows) was seen on image **B**, indicating progressive disease.

Functional Magnetic Resonance Imaging Techniques

Several MRI techniques, such as dynamic contrast-enhanced MRI (DCE-MRI), diffusion-weighted imaging, and MR spectroscopy, have been evaluated as a marker of tumor response. As of yet, there are no standardized protocols or clearly defined cutoffs for objective assessment of tumor response with these techniques. Most of the data regarding these techniques have come from single-center, predominantly retrospective studies and need to be validated in larger prospective randomized studies.

DCE-MRI involves acquisition of serial images before, during, and after intravenous administration of low-molecular weight gadolinium chelate. Typically, each image set is obtained with a temporal resolution of only a few seconds. DCE-MRI measures tissue vascularity when it is performed with T1-weighted contrast-enhanced techniques.²⁶ Other less widely used techniques of MR perfusion include dynamic susceptibility contrast-enhanced MRI, which assesses changes in T2* during the first-pass of gadolinium, and noncontrast arterial spin labeling. T1-weighted DCE-MRI may be performed semi-quantitatively, yielding parameters that may be obtained directly from the signal intensity–time plot, such as time to peak concentration and slope of enhancement curve. Such parameters are highly dependent on type of scanner and scan protocol used. In addition, the signal intensity is not proportional to the gadolinium concentration in tissue. In an effort to offer a greater degree of uniformity between different studies, quantitative techniques were developed. The details of the quantitative techniques, including the measurement of arterial input function and types of models used, are beyond the scope of this text and discussed elsewhere.^{26–30} A frequently used model (Toft's model) assumes that gadolinium infuses freely between the plasma and extravascular extracellular space and yields parameters such as the wash-in rate (K^{trans}), washout rate (K_{ep}), and fractional extracellular space volume (v_e).³⁰

Most studies on DCE-MRI have been performed in the pelvis (female gynecologic cancers, rectal or prostate cancers). Respiratory motion in the upper abdomen makes high temporal resolution DCE-MRI technically challenging. A few studies

have shown that high pretreatment K^{trans} indicates a better response of abdominal tumors to chemotherapy or antiangiogenic therapy.³¹ These results are concordant with studies on head and neck, brain, and breast cancers.^{26–28,32,33} A dramatic drop in K^{trans} after therapy is also suggestive of good response. Nevertheless, standardization of methodology and more widespread verification of results are required before DCE-MRI may be used clinically for tumor response assessment.

Diffusion-weighted MRI has been explored as a potential tool for response assessment in primary and metastatic liver disease, pancreas cancer, and rectal cancer.^{34,35} The results of these studies are somewhat discordant. Low pretreatment apparent diffusion coefficient (ADC) was shown to be a predictor of poor response in pancreas cancer, whereas high pretreatment ADC was shown to indicate therapy failure in liver metastasis and primary rectal cancer.^{36–38} An increase in ADC has been shown to correlate with good response in hepatocellular cancer treated with targeted therapy and in colorectal liver metastases treated with chemotherapy.^{39,40} However, the optimal timing of scans is unknown. ADC changes may reflect pathologic changes to the tumor tissue after treatment. A decrease of ADC value may be observed in the first 24 to 48 hours after treatment, probably because of cytotoxic edema and reduced extracellular space. In the first 2 weeks, tumor necrosis results in an increase of ADC values, which is often seen before tumor size change is measurable. A subsequent reduction in ADC values may be related to a cellular inflammatory exudate, tumor repopulation, fibrosis, or decreased perfusion.⁴¹ Further research is required before diffusion-weighted imaging is clinically used for assessment of tumor response.

Conclusion

Imaging plays a crucial role in the assessment of tumor response to various therapies. The advent of molecular targeted therapy has increased the need to determine tumor biology, which may not correlate with changes in tumor size. At present, RECIST 1.1 is the predominant method of formally assessing tumor response. In the future, techniques that involve PET or functional MRI may be used to overcome the limitations of anatomic measurements.

 magnetic resonance colonography on, 930
 small bowel, 865-866, 867f, 875f
 Endoscopic heater probe therapy, 496, 499f
 Endoscopic retrograde cholangiopancreatography (ERCP), 1184, 1281, 1297, 1297f, 1303-1324
 on AIDS-related disorders, 1634
 on biliary postoperative complications, 1451-1452
 biliary tract infection and inflammation in, 1311-1320
 biliary tract neoplasias in, 1306-1311
 of Caroli's disease, 606-607, 606f
 on choledochal cysts, 1345
 of choledocholithiasis, 1371
 in common duct stone removal, 1308
 complications of, 1321-1322
 cost per correct diagnosis of, 1335
 indications for, 1781
 liver, on cystadenomas and cystadenocarcinomas, 1583, 1583f
 magnetic resonance cholangiopancreatography compared with, 1323
 normal anatomy in, 1304f
 biliary tract, 1303-1306, 1304f
 pancreatic duct, 1305-1306, 1306f
 pancreas
 on annular pancreas, 1805
 examination techniques in, 1781
 inflammation in, 1321, 1321f
 neoplasias in, 1187-1189
 on pancreas divisum, 1801-1802
 pancreatic duct strictures, 1891
 on pancreatitis, acute, 1812
 on pancreatitis, chronic, 1823-1826
 on trauma, 1859-1860
 pancreatitis from, 1815f
 pediatric, 2180, 2216
 percutaneous transhepatic cholangiography versus, 1295-1296
 on primary sclerosing cholangitis, 1428, 1429f
 technique for, 1303
 Endoscopic sclerotherapy, 431-432, 460
 Endoscopic studies
 on Barrett's esophagus, 305, 377
 on *Candida* esophagitis, 312-313
 capsule

Endoscopic studies (Continued)

- on acute small bowel bleeding, 841
- computed tomography enterography with, 684
- on gastrointestinal hemorrhage, 2272-2273
- integration of with computed tomography enterography, 692
- small bowel neoplasms on, 689
- esophageal, with epidermolysis bullosa dystrophica, 337-338
- esophageal perforation from, 413-414, 415f
- for gastrointestinal hemorrhage, 2272
- glutaraldehyde-induced injuries from, 342-343, 344f
- on herpes esophagitis, 316-317
- on Kaposi's sarcoma, 592
- on MALT lymphomas, 581
- for peptic ulcer diagnosis, 477-479
- postoperative gastric and duodenal, 631
- treatment of ulcers with, 486-487
- video capsule, 726-727, 728f

Endoscopic ultrasound (EUS)

- in esophageal cancer staging, 380-381, 383-385
- of esophageal leiomyosarcomas, 405
- of gastric carcinoma, 562-565, 563f
- of gastric carcinomas, 562-565, 563f-564f
- in gastric lymphoma staging, 585-586
- of gastroduodenal lymphomas, 585-586
- linear array, 1802
- of lymph node metastasis, 387f
- normal esophageal, 386f
- pancreas
 - on ductal adenocarcinomas, 1882
 - on pancreatitis, chronic, 1825
 - surgery and, 1863
- on pancreas divisum, 1802
- staging criteria in, 384-385
- technique, 383

Endovascular intra-arterial therapies

- drug-eluting bead chemoembolization, 1513
- for liver malignancies, 1510-1513
- transarterial chemoembolization, 1510-1513, 1512f

Endovascular transcatheter embolization, 1909-1910

Entamoeba histolytica, 1773

- hematogenous spread of, 2021
- life cycle of, 1613f
- liver abscesses from, 1611-1614

Enteral access for alimentation, 130-134

Enterectomy, small bowel, 852-855

Enteric duplications, small bowel obstruction by, 817

Enteritis

- acute infectious, 757f
- chemotherapy-related, 763
- HIV, 765
- mesenteric adenitis in, 969
- neutropenic, 765, 765f
- radiation, 843-845, 845f

Enterocoles, 896-898, 897f-898f

- with rectocele and intussusception, 899f
- with sigmoidocele, 899f

Enterocystitis, 9-10, 27-30, 670-672, 676f

- air-contrast, 672-673, 673f, 675f
- anesthesia in, 671
- on appendiceal mucocoeles, 975, 976f
- on appendicitis, 960-961, 961f-962f
- on celiac disease, 762
- chronic diarrhea and, 678

colon

- adenocarcinomas on, 1035-1039, 1035f-1036f
- benign epithelial polyps, 1032-1035, 1034f
- ischemia in, 1114-1116, 1115f
- on obstructions, 1103
- polyp detection with, 1052, 1034f
- postoperative follow-up in, 1029, 1059f

Enterodysia (Continued)

- on colorectal cancer, 1029-1030, 1030f
- postoperative follow-up with, 1058-1060, 1059f
- complications in, 886, 887f
- computed tomography, 694-709
 - historical background of, 694-695
 - indications for and comparisons with other imaging methods, 695-704
 - for Crohn's disease, 695-697, 696f
 - miscellaneous, 701-704, 702f-704f
 - for small bowel neoplasms, 697-699, 697f-698f
 - for small bowel obstructions, 699-701, 699f-701f
- summary on, 705
- technical problems and limitations in, 704-705

disadvantages of, 677-678

diverticulitis findings in, 939, 939f

diverticulosis and, 885

double-contrast, 879-884

- correct preparation in, 882f
- lymphoid follicular pattern on, 883-884, 884f
- materials and equipment for, 880-884
- patient preparation for, 879-880
- routine, 880-883, 880f, 881f-883f

filling of the entire colon in, 886

giant sigmoid diverticulum on, 952, 952f

with granulomatous colitis, 510

hypotonic duodenography, 674-675, 676f

intubation in, 671-672, 672f

on intussusceptions, 1109, 1109f

on Meckel's diverticulum, 861

methylcellulose-contrast, 673-674, 674f-675f

metoclopramide in, 671, 671f

normal small bowel parameters for, 870f

pancreas examination with, 1776

poor preparation for, 882f, 884, 885f

preparation for, 670-671

in salmonellosis, 1017-1018

single-contrast, 672, 674f, 884

on small bowel obstructions, 810-811, 811f

closed loop, 813, 813f

magnetic resonance, 722, 722f

technical problems in, 884-886

technique variations in, 886-887

toxic megacolon from, 1009

on ulcerative colitis, 987-992, 987b

water-soluble contrast agents in, 675-676, 676f

Enterocolitis

acute abdomen from, 2265, 2265f

infectious, 64-65

Enterocolitis

appendicitis differentiated from, 969

mesenteric adenitis in, 969

necrotizing, 1124-1125, 2098, 2103-2106, 2104f-2105f

small bowel transplantation for, 858

Enterocytozoan bienersi, 767

Enterography. See Computed tomography enterography (CTE); Magnetic resonance enterography (MRE)

Enteroliths

obstruction by, 1110

small bowel, 867, 868f

Enteropathy-associated T-cell lymphomas (EATLs), 720

Enteroscopy

- deep, on gastrointestinal hemorrhage, 688-690
- push, on acute small bowel bleeding, 841

Enterostomy, 855

Enterotoxins, 1128

Enzyme-linked immunosorbent assay (ELISA) test, 762

Eosinophilic cholangitis, 1432

Eosinophilic enteritis, 782-783, 783f, 786

Eosinophilic esophagitis, 333-335, 335f

eosinophilic gastroenteritis differentiated from, 313

pediatric, 2132-2133, 2133f

strictures from, 464f

Eosinophilic gastritis, 659f, 1021, 2152

Eosinophilic gastroenteritis, 513-514, 514f, 2152

Eovist, 1715

Epidermoid cysts. See Sebaceous cysts

Epidermolysis bullosa, 336-338, 338f, 2074

differential diagnosis of, 462t

pyloric atresia with, 2138, 2141

strictures from, 464f

Epigastric abscesses, 1276

Epiglottic tilt, 225

Epiglottitis, squamous cell carcinoma of, 249f-250f

Epiploic appendagitis

acute abdomen from, 2263, 2263f

differentiated from appendicitis, 969, 970f

differentiated from diverticulitis, 946, 946f

Epithelial cysts, spleen, 2232

Epithelial hemangioendotheliomas, 1588, 2205-2206

Epithelioid leiomyomas, 534

Epithelium, in Barrett's esophagus, 375

Epstein-Barr virus infection, 777-778, 1753

Erosions, double-contrast studies of, 47, 51f

See also Ulcers

Erosive gastritis, 496-499, 497f-498f

Erythema multiforme major, 338-339

Erythromycin, gastrointestinal effects of, 20

Escherichia coli

with biliary obstruction, 1297

colitis caused by, 1018, 1019f

in emphysematous gastritis, 514-515

in hemolytic uremic syndrome, 2168

in liver abscesses, 1608-1609, 1609f

in obstructive cholangitis, 1134-1135

pyogenic abscesses with, 1272-1273

Esophageal-airway fistulas, 420, 421f

Esophageal bronchus, 2125, 2126f

Esophageal bypass, 389

Esophageal devascularization, 460

Esophageal intramural pseudodiverticulosis, 343-346, 345f-346f

Esophageal papillomatosis, 350, 352f, 463t

Esophageal retraction, 428-429, 428f

Esophageal stents, palliative placement of, 458-459

Esophageal webs, 300

in chronic graft-versus-host disease, 342

differentiated from Schatzki rings, 443

Esophagectomy, 403

Esophagitis. See also Herpes esophagitis

acute alcohol-induced, 341-342, 342f

alkaline reflux, 340-341, 341f

caustic, 330-333, 332f-333f

cytomegalovirus, 318-319, 320f-321f

differential diagnosis of, 462t, 464t

drug-induced, 326-328, 328f-330f, 334t

eosinophilic, 333-335, 335f

eosinophilic gastroenteritis differentiated from, 513

pediatric, 2132-2133, 2133f

strictures from, 464f

focal contact, 317-318

HIV, 319-320, 321f

idiopathic eosinophilic, 333-335, 335f

infectious, 312-325

nasogastric intubation, 339-340, 340f-341f

radiation, 328-330, 330f

rare causes of, 322

reflux (See Reflux esophagitis)

tuberculous, 320-322, 322f-323f

viral, 312

- Esophagogastrectomy, 453-455
 complications with, 454-455
 for leiomyosarcomas, 403
 obstructions after, 451, 451f, 455f
 strictures after, 456f
 transhiatal-transcervical approach in, 454
 transthoracic approach in, 453, 455f
 tumor recurrence after, 454-455, 457f
- Esophagogastric mucosal prolapses, 446, 447f
- Esophagogram, 442f
- Esophagography
 double-contrast, 291
 for esophageal perforations, 415-417
 for GERD, 291
 single-contrast, 25
 of squamous cell carcinoma, 371
